where line labels are given in Figure 1 and k_A and k_X are scaling factors. The quantities ${}^a\nu_A$, ${}^a\nu_{+-+}$, and ${}^s\nu_{+0-}$ are all directly observable from the A spectrum (^{13}C in a $^{13}\text{CH}_2$ study). The quantity ${}^a\nu_A$ is proportional to the sum of the intensities of all the lines in the A multiplet. The quantity ${}^a\nu_{+-+}$ is proportional to the difference between the intensities of the outer and inner lines of the multiplet, while ${}^s\nu_{+0-}$ is related to the difference between the two outer lines of the multiplet. The quantity ${}^a\nu_X$ is simply the total X (^1H) magnetization. Application of a 90° X pulse simultaneous with an observe pulse on the A spins exchanges triplet intensities in the A manifold and allows, by difference, evaluation of ${}^a\nu_{\pm\pm}$.

The elements of the relaxation matrix, $\mathbf{\Gamma}$, are made up of linear combinations of spectral densities arising from the interactions important in the system under study. These might include dipole–dipole, chemical shift anisotropy, spin rotation, and random field interactions among others. The relaxation matrix for the AX_2 spin system including only contributions from dipole–dipole and random field interactions and corresponding to the set of magnetization modes used here is given in full elsewhere.⁴

In the limit of extreme narrowing, the dipolar relaxation of an AX_2 or $^{13}\text{CH}_2$ spin system is completely described by four frequency-independent spectral densities. Two of these are autocorrelation terms related to the CH or HH' internuclear vectors (J_{CH} and J_{HH}). The others are cross-correlation terms relating one CH vector to the other (J_{HCH}) or to the HH' vector (J_{CHH}). A complete set of random field spectral densities would include an autocorrelation term at the carbon (j_C), an autocorrelation term at each hydrogen (j_H), and a cross-correlation term between the two hydrogens (j_{HH}).

Figure 1 (a) The energy level diagram and eigenstates of the static Hamiltonian, $\hat{H}_0$, for an AX_2 spin system. The first label gives the state of the A spin and subsequent labels the states of the two X spins. Allowed single quantum transitions are labeled. (b) A schematic diagram of the AX_2 spectrum in isotropic solution

3 OBTAINING MOTIONAL INFORMATION FROM COUPLED SPIN RELAXATION DATA

As noted above, the spectral densities are the Fourier transforms of correlation functions relating the orientation of an internuclear dipole to a second dipole at a later time. In the simplest case, these correlation functions decay as simple exponentials which can be characterized by a correlation time, τ_c . The value of the spectral density then depends on the magnitude of τ_c and the frequency at which it is sampled. When the dynamics are more complex, the correlation function can be a complex sum of exponentials with various time constants. The resulting spectral densities do not reflect the values of these time constants in any simple way.

Two general approaches to this problem have been established. One is to sample a spectral density function at a range of frequencies, perhaps by performing conventional T_1 experiments at several field strengths. This is often effective in enabling the investigator to estimate the timescales involved in a dynamic process, but is less effective in establishing the associated geometrical factors. The other approach, embodied in the coupled spin relaxation experiment, is to sample a wider variety of spectral density functions. The ratios of the different spectral densities at a given frequency are often a sensitive function of the geometry of the motion.

It remains to establish the relationship between the measured spectral densities and appropriate motional parameters. Again, two approaches have been used. The first, dating to the very first use of spin relaxation to elucidate dynamic parameters, is to assume a particular motional model and then calculate the associated correlation function and, by taking the Fourier transform, spectral density function. The assumption of diffusive isotropic motion, which leads to an exponential correlation function and a Lorentzian spectral density function, is the classic example of this approach, but it has also been applied to much more complex models.

A second approach that has been used recently is to take the four spectral densities measured in the coupled spin relaxation experiment (J_{CH} , J_{HH} , J_{HCH} , and J_{CHH}) and to reexpress them in terms of four autocorrelated Cartesian spectral densities, which are in turn simply related to four correlation times (τ_{xx} , τ_{yy} , τ_{zz} , and τ_{xy}).⁷ These transformations are model-independent and are extremely useful in several ways. First, the difficulty of interpreting cross-correlation functions is removed. Second, the results are presented in a molecule fixed Cartesian axis system commonly used in dynamics simulations (see Figure 2) and are readily interpretable. The correlation times describe the reorientation of geometrical constructs having the shape of d orbitals. Thus τ_{xx} represents the motion of a d_0 construct fixed on the x axis or the bisector of the HCH angle. Lastly, it should be emphasized that in the transformation to this basis no biases or assumptions about the dynamical behavior of the molecule are introduced, as are encountered in using diffusional models.

As will be discussed below, in spin relaxation studies of unlabeled polymers it is difficult to determine J_{HH} reliably. Under these circumstances some assumption must be made in order to accomplish the transformation. A reasonable assumption is to set τ_{xx} and τ_{yy} equal to each other and defining a $\tau_{\perp}$ term. The quantities τ_{xx} and τ_{yy} have been shown to be very similar in value in simulations of flexible chains.

Figure 2 Orientation of the Cartesian axis system in the frame of reference of the methylene group

Reduced spectral densities are defined as

$$\hat{J}_{ijkl} = \frac{20}{9K_{ijkl}} J_{ijkl}(\omega = 0) \quad (5)$$

where $K_{ijkl} = \gamma_i \gamma_j \gamma_k \gamma_l h^2 / r_{ij}^3 r_{kl}^3$ and i, j, k , and l represent the spins involved. If the reduced autocorrelation spectral densities $\hat{J}_{xx}$ and $\hat{J}_{yy}$ are set equal to each other than it can be shown:

$$\left. \begin{aligned} \tau_{\perp} &= \tau_{xx} = \tau_{yy} = \frac{3}{4(\alpha^4 - \beta^4)} (\hat{J}_{AX} + \hat{J}_{XAX} - 4\beta^2 \hat{J}_{AXX}) \\ \tau_{\parallel} &= \tau_{zz} = \frac{3}{2\alpha^2} (\hat{J}_{AX} + \hat{J}_{XAX} - (2 - 4\beta^2) \hat{J}_{AXX}) \\ \tau_{xy} &= \frac{1}{4\alpha^2 \beta^2} (\hat{J}_{AX} - \hat{J}_{XAX}) \end{aligned} \right\} \quad (6)$$

where $\alpha = \cos(\theta/2)$, $\beta = \sin(\theta/2)$, and θ = HCH angle.

4 EXPERIMENTAL METHODS FOR POLYMER STUDIES

Spectroscopic samples are typically 1% w/v polymer in good solvents. Samples are degassed either by flushing the solvent with dry nitrogen and then assembling and sealing the sample under nitrogen, or by subjecting the sample to five freeze-pump-thaw cycles and then sealing under vacuum.

Spin relaxation measurements use variations on the inversion recovery pulse sequence. Four different initial perturbations of the coupled $^{13}\text{CH}_2$ spin system are used: (1) a ^{13}C 180° pulse inverting the ^{13}C triplet; (2) a ^1H 180° pulse inverting the proton doublet; (3) a low power ^1H pulse inverting only the low-frequency line of the ^1H doublet; and (4) a J pulse preparation on the ^1H magnetization (resembling a spin echo) resulting in the inversion of the outer lines of the ^{13}C triplet. In each case the initial perturbation of the spin system is followed by a variable delay period and a ^{13}C sampling pulse as in a normal inversion recovery experiment. For each experiment 17 or 18 different delay times are used. The delay times are ordered randomly to reduce systematic errors. Recycle delays are adjusted to be at least 10-times the nominal T_1 value of the sample.

FIDs are subjected to appropriate exponential multiplication before Fourier transformation. Line amplitudes are then obtained, typically after applying a linear baseline correction over a 500 Hz region centered on the appropriate ^{13}C multiplet. Relaxation parameters are obtained from a multiparameter least squares curve fitting routine using an implementation of the Levenberg–Marquardt algorithm. Theoretical values of the intensities of the modes are calculated first using the normalized, symmetric set of modes described by Werbelow and Grant⁸ and then taking appropriate linear combinations to generate the modes described here. Parameters for the fit include not only dipolar and random field spectral densities, but also several experimental parameters.⁹ To account for any systematic instrumental imperfections or differences in widths of inner and outer lines of the multiplet, the line amplitudes for each data set are scaled by two parameters β and δ such that the ^{13}C multiplet has the expected 1:2:1 intensity ratio when fully relaxed. The term L_3 (see Figure 1) is multiplied by δ to equalize the outer line intensities and then both outer lines are multiplied by β to equalize the intensities of the sum of the outer lines and the inner line of the multiplet. A third parameter associated with each data set is a normalization constant such that $^a\nu_{\text{C}}(\infty)$ is scaled to unity. Additional parameters are pulse efficiencies and differential pulse efficiencies.

Spectral densities included in the fit include four frequency independent spectral densities describing the dipolar relaxation of a methylene group ($^{13}\text{CH}_2$) in the limit of extreme narrowing (J_{CH} , J_{HH} , J_{HCH} , and J_{CHH}). Random field spectral densities are also included to account for other relaxation mechanisms operating in the sample, primarily remote dipolar interactions. For the methylene spin system, a complete set of random field spectral densities would include an autocorrelation term at the carbon (j_{C}), an autocorrelation term at each hydrogen (j_{H}), and a cross correlation term between the two hydrogens (j_{HH}). At high fields or in a more anisotropic electronic environment caused by insertion of an oxygen into the polymer chain, cross correlation between chemical shift anisotropy (CSA) and dipolar relaxation mechanisms is possible. Where appropriate, this requires inclusion of four more spectral densities in the fit: $J_{\text{CH,C}}$, the cross term between the CH dipolar interaction and the carbon CSA; $J_{\text{CH,H}}$, the cross term between the CH dipolar interaction and the proton CSA; $K_{\text{CH,H'}}$, the cross term between the CH dipolar interaction and the CSA on the other proton (H'); and finally $J_{\text{HH,H}}$, the cross term between the HH dipolar interaction and the proton CSA.¹⁰

Rigorous characterization of dipolar interactions as random fields requires that both the rotational and translational motion of the interacting spins be independent. This independence of motion is not satisfied for protons bonded to carbons adjacent to the methylene group of interest. A study of isotopomers of 5- ^{13}C nonane has shown that inclusion of random field terms in the relaxation matrix is not enough to allow accurate measurement of all four dipolar spectral densities in the presence of protons on neighboring carbons.⁹ However, that study showed that as long as the random field term j_{C} is held equal to zero in the fitting procedure, then J_{CH} , J_{HCH} , and J_{CHH} may be reliably evaluated; J_{HH} remains strongly correlated to j_{H} . The results reported here follow this practice.

5 RESULTS FROM POLYMER STUDIES

These methods have been applied to a series of homologous polyethers with increasing numbers of methylenes between the oxygens: poly(oxyethylene) (POM),¹¹ poly(ethylene oxide) (PEO),¹² and poly(tetramethylene oxide) (PTMO),¹² and to poly(*cis*-1,4-butadiene) (CBD).¹³ In the absence of data on polyethylene, CBD serves as a model for the dynamics of the infinite polymethylene chain. Recent simulations of polyethylene and polyisoprene suggest the dynamics are quite similar despite the structural differences and justify this analogy.⁶ Data from the smaller hydrocarbon [11- ^{13}C]heneicosane are also included for comparison.¹⁴ These polymers exhibit a wide range of equilibrium conformations with POM most stable in a helical conformation and CBD in an extended, all-*trans* conformation. PEO and PTMO are more flexible and intermediate in conformational preferences. As such they provide an interesting opportunity to probe the impact of chain conformation on dynamics with only minimal variations in structure.

Each of the polymers studied has a single type of methylene group, except for PTMO which has two distinct types of methylene groups with the carbons adjacent to the oxygen (C- α) absorbing at 67.4 ppm and the central carbons (C- β) absorbing at 25.3 ppm. Only POM and heneicosane were isotopically labeled to provide truly isolated $^{13}\text{CH}_2$ spin systems.

Three ‘magnetization nodes’ of each $^{13}\text{CH}_2$ spin system can be obtained while observing only the ^1H coupled ^{13}C spectrum of a given polymer: $^a\nu_{\text{C}}$, the total ^{13}C magnetization; $^a\nu_{+-+}$, the difference between the inner and outer line intensities of the ^{13}C triplet; and $^s\nu_{+0-}$, the difference between the intensities of the outer two lines of the ^{13}C triplet. Figure 3 shows typical relaxation curves for C- α of PTMO.

The three dipolar spectral densities which have been reliably evaluated in all cases can be reexpressed in terms of three second rank autocorrelation times ($\tau_{\perp} = \tau_{xx} = \tau_{yy}$, τ_{zz} , and τ_{xy}). The transformation to Cartesian correlation times requires that the geometry of the spin system be known. In most cases these geometries must be inferred from small molecule analogs. As hydrogens are not located accurately in most X-ray diffraction studies, it is generally necessary to rely on other structural techniques such as electron or neutron diffraction. For methylenes in hydrocarbon chains, electron diffraction studies of small alkanes provide the HCH angle of 108.5° and a CH distance of 1.12 Å. For protons bonded to carbons adjacent to oxygen, the value of 1.11 Å for the CH distance given by the electron diffraction study of the small molecule analog 1,2-dimethoxyethane has been adopted. The HCH angle was not determined in that study. The Cartesian correlation times calculated using these parameters are given in Table 1. Uncertainties reported are standard errors in the last significant figure of the associated value.

The timescales of tens of picoseconds reported in Table 1 are consistent with those generally found for local segmental motion of polymers in dilute solution. Because of differences in temperature and viscosity among the samples, comparing the absolute values of the correlation times is not as interesting as comparing ratios of correlation times which gives insight into the anisotropy of motion. Table 2 gives these ratios.

If we examine the anisotropies of motion of the most conformationally distinct polymers, POM and CBD, we see

Figure 3 Magnetization mode intensities for C- α of PTMO. Intensity units are defined by setting $^a\nu_C(\infty)$ to unity. Experimental values for $^a\nu_C$, $\blacksquare$; experimental values for $^a\nu_{+-+}$, $+$; experimental values for $^s\nu_{+0-}$, $\blacktriangle$. Solid lines are calculated from fitted parameters. (a) After ^{13}C inversion. (b) After ^1H inversion. (c) After selective inversion of one line of the ^1H doublet. (d) After J pulse preparation of the ^1H spins, resulting in ^1H inversion and inversion of the outer lines of the ^{13}C multiplet

Table 1 Cartesian Correlation Times of Polymers in Solution

	$\tau_{\perp}$ (ps)	τ_{zz} (ps)	τ_{xy} (ps)
POM (phenol- d_6 , 86 °C)	21(1)	36(6)	12.1(8)
PEO (D_2O , 25 °C)	42(9)	115(11)	44(3)
PTMO(C- α) (toluene- d_8 , 28 °C)	21(2)	64(3)	10.4(6)
PTMO(C- β) (toluene- d_8 , 28 °C)	15(2)	45(2)	15.2(6)
CBD (CD_2Cl_2 , 20 °C)	23(2)	55(6)	11(1)
C11-heneicosane (diglyme- d_{14} , 40 °C)	21(1)	48(3)	9(1)

Table 2 Motional Anisotropies of Polymers in Solution

	$\tau_{zz}/\tau_{\perp}$	τ_{zz}/τ_{xy}	$\tau_{\perp}/\tau_{xy}$
POM	1.6	2.6	1.6
PEO	2.7	2.6	1.0
PTMO(C- α)	3.0	6.2	2.0
PTMO(C- β)	3.0	3.0	1.0
poly(<i>cis</i> -1,4-butadiene)	2.4	5.0	2.1
C11-heneicosane	2.3	5.1	2.2

that they are quite different. POM has reduced anisotropies of motion compared with CBD methylenes, which in turn have anisotropies of motion which are very similar to those of the central methylene of the smaller hydrocarbon heneicosane. These differences have been interpreted in terms of the relative importance of transitions between rotational isomeric states and librational motion within a given potential energy well in the spin relaxation of these polymers. The lowest energy conformation of POM in solution is predicted to be helical, with no readily available rotational transitions that do not involve major chain translocation. In such a situation it is reasonable to expect librational motion to be an important relaxation mechanism. In CBD the extended chain structure make possible ‘crankshaft’-type correlated motions of a few bonds. Supporting the interpretation that these might be important are simulations of hydrocarbon chains which show contributions from both correlated and uncorrelated chain motions. The correlated motions in these simulations have a similar ratio of $\tau_{zz}/\tau_{\perp}$ to that observed for CBD and heneicosane.¹⁵

New patterns emerge when examining the anisotropies of motion for PEO and PTMO. Overall the pattern for C- α of PTMO is much like those seen previously in hydrocarbons, although with slightly greater anisotropies. PEO and the C- β position of PTMO have very similar anisotropies of a reduced magnitude and a much different pattern from any observed previously. The ratios $\tau_{zz}/\tau_{\perp}$ and τ_{zz}/τ_{xy} are nearly identical and the ratio $\tau_{\perp}/\tau_{xy}$ is essentially unity. The relative anisotropies of C- α and C- β of PTMO are the opposite of what might be naively expected. Based on the similarity of the energetics of conformations involving C- α and its adjacent atoms to those in PEO, and of conformations involving C- β to those in PE, one might expect the opposite result.

Do the differences in dynamics in PEO and PTMO originate at the librational level or in transitions between rotational isomeric states? It is difficult to imagine that the differences in

Figure 4 Examples of chain motion on a tetrahedral lattice. An example of three bond motion is at the bottom and of four bond motion is at the top

librational motion between C- α and C- β , adjacent carbons in the PTMO chain, are large enough to give rise to the measured difference in anisotropies. A plausible model does exist for differences in rotational transitions.

Geny and Monnerie have simulated the motion of the various linear polyoxides as motions involving three or four bonds on a tetrahedral lattice.¹⁶ Examples of such motions are shown in Figure 4. The three bond motions are essentially the 'crankshaft'-type motions referred to above. Four bond motions involve the pivoting of a segment back and forth, without the option of continuing around the chain axis. Three bond motions occur in all their simulations of the polyoxides although with markedly less 'efficiency' in POM due to the stability of its helical form. Four bond motions such as shown are forbidden in PE due to the 'pentane effect' (which rules out g^+g^- sequences because of steric interactions of the hydrogens on carbon i and $i + 4$ along the chain). In the polyoxides these motions are allowed as long as at least one oxygen atom is at the 'foot' of the pivoting segment. Geny and Monnerie found these motions even more common than three bond motions in PEO, significant in PTMO, and again rarely observed in POM.

Of course, full recognition must be given to the limitations of the model of the polymer chain as moving on a tetrahedral lattice. In this model all motions must be cooperative, in the sense that any configurational transition is accompanied by compensatory transitions elsewhere in order not to force large motions of the chain. In contrast, Brownian dynamics simulations of the PE chain showed that at least two-thirds of the configurational transitions in PE were 'isolated' rotations about bonds along the chain accompanied by orientational relaxation of neighboring segments. Simulations of polyisoprene suggest that three bond motions are largely absent in polyisoprene. Furthermore, analysis of the motion in isolated configurational transitions and in 'three bond motions'

in PE finds them to be nearly identical, leading into question the importance of cooperative motions in analyzing polymer dynamics.

Even so, the reduced anisotropy of PEO relative to the hydrocarbons may be due to the combination of three- and four-bond motions available to the former. In particular, the ratio $\tau_{\perp}/\tau_{xy}$ becomes unity only when there is efficient averaging with respect to the z axis of the coordinate system we have defined. Remembering that the z axis is perpendicular to the HCH plane or parallel to the vector between adjacent atoms on either side of the methylene along the polymer chain, efficient averaging around this axis occurs whenever the methylene is located at the 'point' of the four bond section which is pivoting.

The results for PTMO may then be explained by noting that only C- β can be at the 'point' of the pivoting section when there is an oxygen at the 'foot', making the four bond motion possible. The motion of a methylene at the 'side' of the four bond segment is similar to that caused by a three bond motion and thus although PTMO as a whole appears to undergo three and four bond motions, C- α can only experience 'three bond like' motion and thus is very similar in anisotropy to hydrocarbons studied previously. Thus while four bond motions may be minor components of the overall dynamics, by introducing a distinctly different reorientational motion they may have an apparently disproportionate impact on the measured anisotropy. A more complete analysis of the importance of these motions must await more realistic simulations of the polyoxide chains. A molecular dynamics simulation of PEO in water has been published recently, but it was on a fairly short chain (13 units) and the question of cooperative transitions was not addressed.

1 INTRODUCTION

Most industrially important organic polymer materials are multicomponent systems, like polymer blends (mixture of two polymers) and polymer composites (consisting of a polymer and a filler, usually inorganic, such as silica or talcum). The macroscopic properties of such materials are determined not only by the molecular properties of the polymers, but also by the miscibility, morphology, and structure of the interfaces between the various components. By choosing the right components and controlling the adhesion between them in the interfaces, materials with optimal macroscopic properties can be prepared. Solid state NMR is well suited for studying the microscopic structure of heterogeneous polymer materials, although its inherent low sensitivity is often a limitation, particularly for the study of the interfacial region between the components when they form large domains.

In this article, we shall discuss various solid state NMR techniques that can be used to study the miscibility of and domain sizes in polymer blends.

2 POLYMER BLENDS

In many practical instances, the critical property that is used to classify a polymer blend as miscible or not miscible is the glass transition temperature T_g . A blend with one T_g , in between those of the pure components, is usually classified as miscible and described as a mixed, single-phase material. For a material with a single T_g , it is still possible that domains of the separate components exist. If they do, it is believed that their dimensions are at most 10–20 nm.¹

Solid state NMR is very well suited for investigating the heterogeneity of polymer blends at the scale below 10–20 nm. As with many other applications of NMR, the enormous freedom and flexibility of the NMR experiment has resulted in many different approaches, each employing specific solid state NMR experiments.

3 THE DIPOLAR INTERACTION

All NMR studies of polymer–polymer miscibility have in common that some NMR parameter of one component that is sensitive to the near presence of another component is measured. Although it does happen that the chemical shift of a nuclear spin in component A is affected by the presence of units of component B, most studies rely in some way on the magnetic interaction between neighboring spin dipoles, that is, the dipolar interaction.

For two spins with angular momentum operators $\hat{I}_1$ and $\hat{I}_2$ and internuclear vector $\mathbf{r}_{12}$, the dipolar interaction can be written in the form²

$$\hat{\mathcal{H}}_D = \frac{\gamma^2 \hbar^2}{r_{12}^3} \left[\hat{I}_1 \cdot \hat{I}_2 - 3 \frac{(\hat{I}_1 \cdot \mathbf{r}_{12})(\hat{I}_2 \cdot \mathbf{r}_{12})}{r_{12}^2} \right] \quad (1)$$

or as

$$\hat{\mathcal{H}}_D = \frac{\gamma^2 \hbar^2}{r_{12}^3} (\hat{A} + \hat{B} + \hat{C} + \hat{D} + \hat{E} + \hat{F}) \quad (2)$$

where

$$\left. \begin{aligned} \hat{A} &= \hat{I}_{1z} \hat{I}_{2z} (1 - 3 \cos^2 \theta) \\ \hat{B} &= -\frac{1}{4} (\hat{I}_1^+ \hat{I}_2^- + \hat{I}_1^- \hat{I}_2^+) (1 - 3 \cos^2 \theta) \\ \hat{C} &= -\frac{3}{2} (\hat{I}_1^+ \hat{I}_{2z} + \hat{I}_{1z} \hat{I}_2^+) \sin \theta \cos \theta e^{-i\phi} \\ \hat{D} &= -\frac{3}{2} (\hat{I}_1^- \hat{I}_{2z} + \hat{I}_{1z} \hat{I}_2^-) \sin \theta \cos \theta e^{i\phi} \\ \hat{E} &= -\frac{3}{4} \hat{I}_1^+ \hat{I}_2^+ \sin^2 \theta e^{-2i\phi} \\ \hat{F} &= -\frac{3}{4} \hat{I}_1^- \hat{I}_2^- \sin^2 \theta e^{2i\phi} \end{aligned} \right\} \quad (3)$$

and the angles θ and ϕ define the internuclear vector in an axis system where the external magnetic field is along the z axis. As a result of this dipolar interaction, in general a spin feels a local field due to the presence of other spins. Because the nuclear magnetic moments are small and the magnitude of this local field decreases sharply (r^{-3}) with the internuclear distance, the presence of a nucleus can be felt over short distances, ranging from a few tenths of nanometer to the order of 10 nm, depending on the technique in question. The NMR methods that we shall discuss are therefore excellently suited for studying the miscibility of polymer blends at a scale below 10 nm.

The various NMR techniques can be distinguished in different ways. Here we divide them into really short-range techniques (up to about 0.6 nm) and techniques that are suitable for studying the miscibility of polymers over distances from 0.6 nm to the order of 10 nm.

4 SHORT-RANGE TECHNIQUES

At least five techniques that have been reported for the study of the miscibility of polymer blends fall into the short-range category. They are based on the use of the chemical shift as a local probe, or employ one of the following (solid state) NMR techniques: cross polarization,³ the nuclear Overhauser effect (see *Nuclear Overhauser Effect*), two-dimensional heteronuclear correlation NMR (see *Heteronuclear Shift Correlation Spectroscopy*), or rotor-driven ¹³C spin diffusion (see *Rotating Solids*).

4.1 Short-Range Techniques Based on Carbon-13 Chemical Shifts

The chemical shift of a nucleus is sensitive to the local electron density. When an interaction occurs between the different components in a polymer blend, this may affect the electron density locally near an NMR nucleus and change the chemical shift. Since the spectral resolution in a solid state NMR spectrum is rather low, to observe such a change of chemical shift two conditions have to be fulfilled. First, the interaction between the components of the blend has to be relatively strong. Direct detection of intermolecular interaction in polymer blends has been reported only for cases where hydrogen bonding or charge transfer between the components occurs. The second condition is that the spectrum shows a resolution high enough to detect such changes in chemical shift. In general, such a high resolution has been obtained only with carbon-13 NMR, where the line broadening due to dipolar couplings with protons has been removed by dipolar decoupling (DD) and the line broadening due to chemical shift anisotropy by magic angle spinning (MAS).⁴ Although changes of chemical shift in a solid state proton spectrum, obtained under high-resolution conditions with multiple pulse decoupling and MAS [CRAMPS (see **CRAMPS**)] have been reported for a complex between a polymer and a monomer,⁵ as far as we know, no such studies have been reported for polymer blends.

4.2 Intermolecular Cross Polarization (CP)

In most CP experiments, magnetization is transferred from abundant proton spins I to rare carbon-13 spins S to enhance the carbon-13 signal. This results in relatively strong and highly resolved carbon-13 spectra. However, since the CP transfer is mediated by the short-range dipolar interactions, CP can also be used to detect whether I and S spins are physically near each other.

Many studies of polymer miscibility make use of this fact. Let us assume that in a binary blend one of the components, A, has only spins I and both components A and B have spins S . Further, we assume that in the S -spin spectrum, obtained with the highest possible resolution, at least one S -spin NMR line of component B at frequency ν_B does not overlap with any of the S -spin NMR lines of component A. When in such a situation a CP transfer of magnetization from I spins in component A to S spins in A and B results in intensity at frequency ν_B , then this proves that the S spins responsible for the intensity at ν_B are only a few tenths of a nanometer separated from an I spin. Situations are also found where only component B has S spins.

The distinction between the different studies that have been reported with this technique lies in the choice of nuclear spins I and S . A popular approach is to perdeuterate one of the components in the blend, say B.⁶ Both components contain carbon-13 spins, and ^1H - ^{13}C CP from protons in A to carbons in B can establish whether or not the two components are mixed on a molecular scale. Direct cross polarization between protons and deuterons can also be employed.⁷ A disadvantage of this technique is that the miscibility between two polymers may be affected when one of the components has to be deuterated. In fact, it has been reported that even polymer isotope mixtures are not simple mixtures.

The blend poly(vinylidene fluoride)/poly(methyl methacrylate) (PVDF/PMMA) has been investigated in great detail with ^{19}F - ^{13}C cross polarization and ^{19}F - ^1H - ^{13}C double cross polarization.⁸ Figure 1 shows the ^{13}C spectrum of the PVDF/PMMA 40/60 blend, obtained from ^{19}F - ^{13}C cross polarization with proton decoupling and magic angle spinning. The small lines of PMMA in this spectrum show the presence of PMMA units near fluorines of PVDF.

An important aspect of the CP technique for the study of blends is to obtain distance information from such experiments. For a perfectly tuned CP process between N_I abundant I spins (spin quantum number I) and N_S dilute S spins (spin quantum number S) the signal intensity of the S

Figure 1 (a) Carbon-13 spectrum of a PMMA/PVDF 60/40 blend, obtained with $^{19}\text{F} \rightarrow ^{13}\text{C}$ intermolecular cross polarization (fluorine spins in PVDF; carbon-13 spins in both PVDF and PMMA), proton decoupling and magic angle spinning. (b, c) Carbon-13 CP MAS NMR spectra of the PVDF (b) and PMMA (c) components, obtained with $^1\text{H} \rightarrow ^{13}\text{C}$ cross polarization. By comparing the blend spectrum with the spectra of the individual blend components, it is clear that a substantial fraction of the PMMA $\text{C}=\text{O}$, OCH_3 and CH_3 groups are within a few tenths of a nanometer away from a PVDF fluorine. The quaternary carbon of PMMA (indicated by C in (c)) is not detected in the blend, since the fluorine-quaternary carbon distance is too large

spins, $I_S(t)$, as a function of the $I \rightarrow S$ CP transfer time t can be expressed as⁹

$$I_S(t) = \frac{I_S(\infty)}{a_+ - a_-} \left[\exp\left(\frac{-a_-t}{T_{IS}}\right) - \exp\left(\frac{-a_+t}{T_{IS}}\right) \right] \quad (4)$$

where

$$\left. \begin{aligned} a_{\pm} &= a_0 \left(1 \pm \sqrt{1 - b/a_0^2} \right) \\ a_0 &= \frac{1}{2} \left(1 + \varepsilon + \frac{T_{IS}}{T_{1\rho}^I} + \frac{T_{IS}}{T_{1\rho}^S} \right) \\ b &= \frac{T_{IS}}{T_{1\rho}^I} \left(1 + \frac{T_{IS}}{T_{1\rho}^S} \right) + \varepsilon \frac{T_{IS}}{T_{1\rho}^S} \\ \varepsilon &= \frac{N_S S(S+1)}{N_I I(I+1)} \end{aligned} \right\} \quad (5)$$

T_{IS} is the CP transfer time and $T_{1\rho}$ the spin–lattice relaxation time in the rotating frame for the I or S spins. $I_S(\infty)$ is the maximum S -spin magnetization available through CP in the absence of relaxation processes. Demco et al.¹⁰ have approximated the CP rate T_{IS}^{-1} as

$$T_{IS}^{-1} = \frac{1}{2} M_{2,SI} J_X \quad (6)$$

where

$$M_{2,SI} = \frac{\langle \Delta\omega^2 \rangle}{4\pi^2} \quad (7)$$

is the van Vleck second moment of the S -spin resonance line determined by the dipolar coupling of the S spins with I spins, and J_X is the cross polarization spectral density function of the I spins. The second moment expresses the static dipolar interaction between S and I spins, while the spectral density function is determined by fluctuations in the I -spin system due to spin flip–flop transitions induced by the B term of equation (2). The spectral density function can be approximated by assuming a Gaussian shape for the correlation function,¹⁰ leading to the following expression for J_X :

$$J_X = \frac{1}{2} \sqrt{\pi} \tau_c \quad (8)$$

where τ_c is the correlation time, which is of the order of the I -spin T_2 and can be estimated from the I -spin linewidth. The second moment can be described, according to Slichter,² as

$$\langle \Delta\omega^2 \rangle = \frac{1}{3} \gamma_I^2 \gamma_S^2 \hbar^2 \left(\frac{\mu_0}{4\pi} \right)^2 I(I+1) \sum_{I,S} (1 - 3 \cos^2 \theta_{IS})^2 r_{IS}^{-6} \quad (9)$$

in which r_{IS} is the distance between I and S spins and θ_{IS} the angle between the internuclear vector and the external field direction. For a given S spin, the second moment contains contributions from all I spins that are dipolar-coupled to this S spin. Because of the r^{-6} dependence of the second moment, the summation in equation (9) can be limited to nearest neighbors. For a polycrystalline solid with the powder average of $1 - 3 \cos^2 \theta_{IS}$,

$$\langle \Delta\omega^2 \rangle = \frac{4}{15} \gamma_I^2 \gamma_S^2 \hbar^2 \left(\frac{\mu_0}{4\pi} \right)^2 I(I+1) \sum_{I,S} r_{IS}^{-6} \quad (10)$$

From a CP experiment where the S -spin signal intensity is measured as a function of the contact time t , T_{IS} can be determined from the fit of equation (4) to the experimental data. For an accurate determination of T_{IS} , the carbon-13 and proton $T_{1\rho}$ have to be measured in separate experiments. Once the CP time T_{IS} and the correlation time τ_c are known, the term

$$\sum_{I,S} r_{IS}^{-6} \quad (11)$$

can be calculated using equations (6), (8), and (10). In particular, for the situation of a polymer blend where we cross polarize from I spins in one component to S spins in the other, we can expect that one I – S distance is shorter than all others. Owing to the r^{-6} dependence, it then seems reasonable to approximate the sum in equation (11) by

$$\sum_{I,S} r_{IS}^{-6} \approx \langle r \rangle_{IS}^{-6} \quad (12)$$

where $\langle r \rangle_{IS}$ is the average nearest I – S distance.

By combining equations (6), (8), (10), and (12), and taking $I = \frac{1}{2}$, we find for protons and carbon-13 spins,

$$\begin{aligned} \langle r \rangle_{IS} &= \left[\frac{1}{80} \pi^{-3/2} \gamma_I^2 \gamma_S^2 \hbar^2 \left(\frac{\mu_0}{4\pi} \right)^2 \tau_c T_{IS} \right]^{1/6} \\ &= (7.8 \times 10^{-53} \tau_c T_{IS})^{1/6} \end{aligned} \quad (13)$$

For the PVDF/PMMA⁸ blend, a PVDF fluorine–PMMA carbon average distance of about 0.3 nm has been found, independent of composition.

In practical situations, the range of T_{IS} values that can be measured is limited by the length of the proton and carbon-13 $T_{1\rho}$ values. We can therefore estimate the longest $\langle r \rangle_{IS}$ that one can hope to find from a CP experiment. When we assume that in most cases T_{IS} values longer than about 30 ms cannot be determined, we find for the ^1H – ^{13}C distance in a rigid proton system with $\tau_c = 1$ ms a value of

$$\langle r \rangle_{\max} \approx 0.36 \text{ nm} \quad (14)$$

4.3 Nuclear Overhauser Effect

Two-dimensional nuclear Overhauser effect spectroscopy (2D NOESY) is an important technique for structural and conformational analysis of biomacromolecules in solution. The nuclear Overhauser effect (NOE) also plays an important role in a number of blend NMR studies. An early example is the work of Douglass and McBrierty,¹¹ who exploited the transient NOE in blends of PVDF and PMMA and of PVDF and poly(ethyl methacrylate) (PEMA). Here, because of the effects of spin diffusion, these experiments should be classified as belonging to the long-range category. White and Mirau¹² used the NOE technique in a one-dimensional fashion to study the miscibility of deuterated polystyrene (PS) and poly(vinyl methyl ether) (PVME) in the solid phase. They were able to show that the motion of the methyl group protons in PVME modulates the dipolar local field at the PS phenyl ring carbons in blends cast from toluene, in contrast to blends cast from chloroform.

4.4 Two-Dimensional ^{13}C - ^1H Correlation NMR

In order to correlate in a two-dimensional fashion a high-resolution carbon-13 spectrum with a high-resolution proton spectrum for solids, three conditions have to be fulfilled:

1. during the evolution period, the proton-proton and proton-carbon dipolar couplings and the proton chemical shift anisotropy have to be eliminated;
2. during the mixing period, coherence has to be transferred from the proton spins to the carbons; and
3. during the detection period, a high-resolution carbon-13 spectrum has to be acquired.

Figure 2 shows a two-dimensional ^{13}C - ^1H correlated spectrum of poly(vinylphenol) and poly(methyl acrylate).¹³ During the evolution time, homo- and heteronuclear dipolar couplings are eliminated by appropriate multiple pulse sequences. The carbon-13 spectrum is obtained under proton-decoupling conditions, while MAS eliminates all line broadenings due to proton and carbon chemical shift anisotropies. Since the distance-determining step is basically a one-step process mediated by the dipolar coupling between protons and carbons, this technique should be listed under the techniques that can provide information about short-range effects. From the spectrum in Figure 2, a direct interaction between the hydroxyl hydrogen of poly(vinylphenol) and the carbonyl carbon of poly(methyl acrylate) can be deduced.

4.5 Rotational Resonance

Although rotational resonance or rotor-driven ^{13}C spin diffusion is an example of the spin diffusion methods discussed in the next section, it is mentioned here since the distance between molecules that can be bridged by this technique falls in the range covered in this section. Owing to the presence of the B term in the dipolar interaction, two spins I_1 and I_2 can undergo flip-flop transitions. When the two spins I_1 and I_2 are both carbon-13 spins under ^1H -decoupling conditions, the probability of such transitions is negligible, unless the coupling B term is at least of the same order of magnitude as $\Delta\delta$, the difference in chemical shift (in energy units) of the two spins. Without ^1H decoupling, the proton-carbon dipolar interactions can help to bridge this energy difference $\Delta\delta$. Even in the last case, spin diffusion between ^{13}C spins at natural abundance is relatively slow and not so attractive for the study of the miscibility of polymer blends. For carbon-enriched systems, the average dipolar interaction is drastically increased, and carbon-carbon spin diffusion times are reduced by two orders of magnitude. Spin exchange between two carbons of two components in a blend can then be used to obtain information about specific nearest-neighbor interactions. We shall not discuss this technique here, since a good overview has been given by Linder et al.¹⁴ We do discuss another technique for enhancing the carbon-carbon flip-flop rate,

Figure 2 Two-dimensional ^1H - ^{13}C correlation spectrum of a 1:1 molar blend of poly(vinylphenol) and poly(methyl acrylate). The carbonyl resonance at 176 ppm is correlated with the hydroxyl proton at 5.0 ppm, as indicated. Surprisingly, the C-4 carbon does not seem to correlate with the C-3 proton. (Reprinted, with permission, from White and Mirau¹³)

Figure 3 Two-dimensional rotor-driven ^{13}C spin diffusion spectra of annealed 50/50 blends of a random copolyester Vectra-A, containing 73% *p*-hydroxybenzoic acid and 27% hydroxynaphthoic acid, and poly(ethylene terephthalate) (PET). The one-dimensional ^{13}C MAS spectrum is shown at the top, with aliphatic PET resonances and quaternary Vectra-A carbons marked P and V, respectively. The small cross peaks between the P and V diagonal lines indicate intimate mixing. (Reprinted, with permission, from Tang et al.¹⁵)

namely, rotor-driven spin diffusion or rotational resonance (see *Rotating Solids*). This experiment can be employed to study the miscibility in blends by using a standard two-dimensional exchange experiment.¹⁵ When the magic angle spinning frequency is tuned to the frequency difference of two carbons C_A and C_B , where C_A is in component A and C_B in component B, then the occurrence of cross peaks between the diagonal lines of C_A and C_B implies miscibility on a molecular scale between polymer A and polymer B. So far, only carbon-13 enriched samples have been used, and an example is given in Figure 3.¹⁵

5 LONG-RANGE TECHNIQUES

5.1 Spin Diffusion

All long-range techniques rely in some way on the process of spin diffusion. Spin diffusion is, like rotational resonance, a consequence of the B term in the dipolar interaction, equation (2). For a large network of dipolar-coupled spins, the effect of successive energy-conserving spin flip-flops can be described as a diffusion process where a local disturbance of the spin system (a nonequilibrium value of the spin magnetization) is dissipated to sites spatially removed from the original disturbance.

A radial spin diffusion process with an isotropic diffusion constant D can be described by the diffusion equation¹⁶

$$\frac{\partial m(r, t)}{\partial t} = D \frac{\partial^2 m(r, t)}{\partial r^2} \quad (15)$$

where $m(r, t)$ is the magnetization at time t at position r . For spherical diffusion from a point source at $r = 0$, the solution of equation (15) is¹⁶

$$m(r, t) = \frac{m_0}{8(\pi Dt)^{3/2}} \exp\left(-\frac{r^2}{4Dt}\right) \quad (16)$$

where m_0 is the total magnetization. The fraction of the magnetization in the volume $4\pi r^2 dr$ between two spheres with radii r and $r + dr$, respectively, at time t is

$$4\pi r^2 dr \frac{m(r, t)}{m_0} \quad (17)$$

The mean-square distance $\langle r^2 \rangle$ that this magnetization has moved from the point source in a time t is given by

$$\langle r^2 \rangle = \int_0^\infty 4\pi r^4 \frac{m(r, t)}{m_0} dr = 6Dt \quad (18)$$

To simplify the problem, we assume that after a disturbance at some point, spin diffusion during a time period t can equalize the magnetization in a spherical domain of radius $\sqrt{6Dt}$. Some workers have assumed a lamellar morphology for polymer blends, and spin diffusion must then be described as a one-dimensional process. Since the root-mean-square distance traveled for such a linear process differs by only a small factor from the three-dimensional case, we shall not worry here about the best model, and shall simply assume that the three-dimensional model describes spin diffusion in polymer blends. For a recent and more extensive discussion of spin diffusion in heterogeneous solids, see Clauss et al.¹⁷

As equation (18) shows, the process of spin diffusion can provide information about domain sizes in polymer blends. Although spin diffusion may occur in every spin system, it will be clear that the diffusion rate can be relatively high only for dense systems with like spins. For carbon-13 spins, for example, the average dipolar interaction is relatively small because of the large average internuclear distances associated with a natural abundance of 1.1%. For such spins, the spin diffusion is almost negligible, especially because in general the dipolar interaction is much smaller than the chemical shift differences. Although one can think of several experiments that eliminate this chemical shift difference, thereby increasing the spin diffusion rate by more than one order of magnitude (e.g., spin locking,¹⁸ and rotational resonance, see Section 4.5), we shall not consider them here. We limit ourselves in the discussion in this section to spin diffusion among proton spins.

We can distinguish

1. direct spin diffusion experiments where the rate of diffusion during a certain time is measured; and
2. indirect experiments where some other parameter is measured whose magnitude is determined by spin diffusion.

A direct experiment always consists of two parts. In the first, the spins are prepared in such a way that different domains have different magnetizations. In the second, spin diffusion restores equilibrium, and the rate of this relaxation process is measured and related to an equation like equation (18). We shall first discuss the direct experiments and the different ways in which the magnetization gradient can be generated and how spin diffusion is manifested.

5.2 Direct Spin Diffusion Experiments

For a direct proton spin diffusion experiment on a binary polymer blend A/B, proton spins in A have to differ in some respect from spins in B, for example, because of a different chemical shift, or because of a difference in relaxation behavior. In the case of a different chemical shift, two possible ways are open: a two-dimensional experiment or selective excitation. An early example of the study of the miscibility in polymer blends is the two-dimensional proton experiment by Caravatti et al.¹⁹ In this Jeener exchange experiment²⁰ on PS/PVME blends, the aromatic protons of PS and the aliphatic protons in PVME are distinguished in the evolution and detection period by eliminating the line broadening due to dipolar interactions and chemical shift anisotropy in a CRAMPS experiment, while during the mixing period, spin diffusion takes care of the exchange of magnetization between PS and PVME protons. The occurrence of such spin diffusion, and the proof that the two components are mixed on a molecular scale, is shown by the presence of cross peaks in the two-dimensional spectrum, reproduced in Figure 4. The same authors²¹ showed for the same blend that the spectral resolution also allowed selective excitation experiments, from which it could be confirmed that the PS/PVME blend can be described as a three-phase system.

In these experiments, magnetization differences are generated among the proton spins, and also the proton spins are detected. An obvious extension of this experiment is to monitor the progression of proton spin diffusion via cross polarization to the carbon spins. The much higher resolution in the carbon-13 spectrum can be exploited to improve the selectivity.^{17,22,23}

A much-used technique to study proton spin diffusion is based on differences in mobility of the two components forming a binary blend. In the original approach of Goldman and Shen,²⁴ a magnetization gradient can be achieved based on the different dipolar strengths of the two components due to molecular motions. Since the dipolar interaction is orientation-dependent, a relatively fast molecular motion may partly or completely average out the dipolar interaction. This means that, for a blend where the two components exhibit significantly different molecular mobilities, the transverse magnetization of one component decays much faster than that of the other. A magnetization gradient is then created, which spin diffusion tries to eliminate. This has been recently used by Spiess and co-workers²³ in a two-dimensional experiment (WISE, *wide line separation*). In the two-dimensional spectrum, the wide line proton spectrum appears along one axis, with the high-resolution spectrum of the carbon-13 spins coupled to the protons in the other dimension. When two components in a heterogeneous polymer system have different proton linewidths, or different proton T_2 values, this creates a magnetization gradient in the evolution time. By inserting a variable mixing time

Figure 4 Two-dimensional proton spin diffusion spectra of blends of polystyrene (PS) and poly(vinyl methyl ether) (PVME): (a) cast from chloroform; (b) cast from toluene. Strong cross peaks between aromatic PS protons and OCH and OCH₃ PVME protons appear in spectrum (b). (Reprinted, with permission, from Caravatti et al.¹⁹)

between the evolution and detection period, proton spin diffusion can be detected via the high-resolution carbon spectrum, and domain sizes can be determined.

Of course, the decay of the transverse magnetization described by a T_2 relaxation time is just one of the relaxation processes, and differences between other relaxation parameters can also be exploited to generate magnetization gradients.

5.3 Effects of Indirect Spin Diffusion

The most common technique for the study of miscibility in polymer blends uses the fact that when the two separate components have different proton relaxation times (mostly T_1 and $T_{1\rho}$ are used), spin diffusion between protons in the blend may or may not equalize the two values, depending on the size of the domains. The procedure is simple:

measure the appropriate relaxation time and compare it with the component values. There are two limiting possibilities: the blend relaxation process can be described by a single exponential or by two exponentials. In the first case, one can assume that the domains are small enough for spin diffusion to average the values from the two components; in the latter case, the domains are too large for spin diffusion to equalize the individual relaxation times. When the relaxation times of component A and B are T_A and T_B , the blend relaxation time T_k averaged by spin diffusion can then be written as

$$T_k^{-1} = p_A T_{kA}^{-1} + p_B T_{kB}^{-1} \quad (19)$$

where p_A and p_B represent the relative proton signal intensities for components A and B, and T_k is T_1 or $T_{1\rho}$.

From our equation (18), we can immediately estimate the limiting size L_D of the domains by realizing that spin diffusion can proceed during a time of the order of the appropriate relaxation time T_k :

$$L_D = \sqrt{\langle r^2 \rangle} = \sqrt{6DT_k} \quad (20)$$

The diffusion coefficient D depends on the density of the proton spins and the proton linewidth. It is generally assumed that D scales as the one-third power of the proton density.²⁵ In many systems, D is of the order of 10^{-15} – 10^{-16} m² s⁻¹; for polyethylene, for instance, $D = 6.2 \times 10^{-16}$ m² s⁻¹.²⁵ When we take for D an average value of 5×10^{-16} m² s⁻¹, for the proton $T_{1\rho} = 10$ ms, and for the proton $T_1 = 1$ s, we find for L_D in the case of $T_{1\rho}$ experiments (remember that for spin diffusion in the rotating frame, D is scaled by a factor of one-half),

$$L_D(T_{1\rho}) \approx 4 \text{ nm} \quad (21)$$

and for T_1 experiments,

$$L_D(T_1) \approx 50 \text{ nm} \quad (22)$$

With these values, one can make a quick estimate of domain sizes in a blend by measuring proton T_1 and $T_{1\rho}$ values. Assuming that the component relaxation times are sufficiently different, one has the following possibilities:

1. the blend has one proton T_1 and one proton $T_{1\rho}$, implying that domains, when present, are smaller than 4 nm and that there is molecular mixing;
2. the blend has one proton $T_{1\rho}$ and two T_1 's, implying that average domain sizes are between 4 and 50 nm;
3. the blend has two values for each type of spin–lattice relaxation time T_1 and $T_{1\rho}$, implying that the average domain size is larger than 50 nm.

So far, we have discussed only proton spin–lattice relaxation, but further information about miscibility can also be obtained from carbon-13 relaxation parameters. However, because, in general, carbon-13 spin diffusion, as discussed above, is a very slow process, the information from such experiments is not usually as clear as that from proton measurements. Therefore, we shall not discuss such experiments here.

A significant improvement of the proton spin–lattice relaxation experiment for determination of miscibility can be

obtained when the actual detection of the proton signal is made indirectly via the carbon-13 spins.²⁶ For that purpose, at the end of the spin–lattice relaxation measurement, one transfers proton magnetization to the carbon spins via cross polarization. When one component of the blend has at least one carbon-13 NMR line that does not overlap with the carbon lines of the other component, the proton relaxation of that component can then be measured separately. In that way, there is no need to decompose proton spin–lattice relaxation curves in order to see whether there is one relaxation time or two.

5.4 Dynamic Nuclear Polarization (DNP)

So far, we have discussed NMR techniques that are suitable for investigating miscible blends, or, in other words, blends where the total interface area between the components is very large. For immiscible blends, all the techniques we have discussed so far do not work, because the interface area is too small and the number of spins in these interface areas is not large enough to be detected. NMR is basically a bulk technique. With DNP, it is possible to enhance the signal from nuclei in interfaces between polymer components, one of which has unpaired electrons. In this way, two advantages are obtained: first, since the DNP mechanism again relies on the dipolar interaction—this time between electron spins and nuclear spins—the nuclear spins that are influenced by the DNP process have to be close to the interface; secondly, the detection limit of such spins is appreciably lowered. This technique has been applied to polyacetylene/polyethylene²⁷ and to polystyrene/polycarbonate blends.²⁸ For a discussion of the DNP effect and the application to blends, we refer to these publications. Here it suffices to say that the experiment is rather involved, while, in addition to the normal solid state carbon-13 NMR experiment with magic angle spinning, one also has to saturate the electron spin resonance (ESR) line of the unpaired electrons. The success of the DNP method is further crucially determined by the ESR linewidth and other parameters. For the cases where it works, it is a unique method, since one can observe spins in areas that are not usually accessible to NMR observation but are of great interest in polymer research.

The DNP process can be used for direct electron–carbon-13 transfer or for electron–proton transfer, followed by proton spin diffusion and proton–carbon-13 transfer via CP. The problem with the first process seems to be that carbons with strong enough coupling with the electrons to show DNP enhancements also have, because of this interaction, broadened NMR lines.²⁸

6 OTHER NMR METHODS

In the proceeding two sections, we have discussed the main methods for studying miscibility of polymer blends by solid state NMR. However, other techniques are certainly worth mentioning. VanderHart et al.²⁹ have shown that in a mixture where one component is deuterated and the mixing is not intimate the dilute protons in the 98–99% deuterated component show a MAS spectrum with a centerband and spinning sidebands on top of the broad proton spectrum from the protonated component. In the case of intimate mixing, when the environment of the deuterated units contains

Figure 5 Proton NMR image of a blend of polybutadiene (PB) and polystyrene (PS) obtained with magic angle spinning imaging. The rigid PS escapes detection; the density of PB is indicated³⁴

protons from the protonated component, there is a significant weakening of or complete disappearance of the spinning sideband pattern.

Xenon-129 NMR has also been used to study polymer blends.^{30,31} It is well known that the chemical shift of Xe is very sensitive to its environment, and when the Xe atoms reside in the free volume of an immiscible polymer blend, it may show more than one line at temperatures low enough that no rapid exchange takes place between the different adsorption sites.³²

A final technique to be mentioned is that of NMR imaging. The problem with this technique is the low inherent sensitivity of NMR and consequently the poor spatial resolution. Therefore, NMR imaging cannot give information about molecular mixing in polymer blends. However, the combination of imaging with further discrimination with the help of NMR parameters like relaxation times or chemical shift makes it an attractive alternative to microscopy for studying noncompatible blends. Some images of heterogeneous materials have been published.^{33,34} Figure 5 shows the image of a polybutadiene/polystyrene blend obtained with magic angle spinning imaging.³⁴

1 INTRODUCTION

The statistical structure of linear polymers in dilute or semi-dilute solution, whose main characteristic is its fractal dimension, has been the subject of extensive studies in modern times, on both theoretical and experimental levels. The interest it raised in physics is because, as a branch of theoretical statistical physics, it is amenable to extremely clean and elaborate treatments making use of sophisticated mathematical techniques.^{1–3} It also offered an ample field for experimentation. One of the most sensitive and most extensively used tools for these polymer studies is small angle neutron scattering (SANS), which yields the Fourier transform of the average space correlation of pairs of nuclei. This kind of approach corresponds to an exploration of the reciprocal or k space of the polymers.

NMR has been largely absent so far from this class of problems; there are a few exceptions. The numerous NMR studies of polymers (for example, see the articles on polymers in the *Encyclopedia of NMR*) are centered on different properties of these systems. The first exception is the use of dynamic polarization in partly protonated and partly deuterated polymers in solid glassy solutions, in connection with SANS, whose unique quality is that it enables one to change continuously the neutron scattering *amplitude* by the polarized nuclei, an enormous advantage for disentangling the various contributions to the neutron scattered intensity.^{4,5} The second exception is mentioned later.

The approach described is to study the influence of the average polymer structure on the characteristics of spin-lattice relaxation.^{6,7} More precisely, we study nuclear relaxation without spin diffusion, under the influence of paramagnetic centers, in polymers in solution in a solid glass. The advantage of this is that, since the various spins relax independently of one another, we can see the sum of the individual magnetization evolutions, which is an additive phenomenon. Therefore, the bulk evolution under relaxation of the NMR signal reflects the statistical structural distribution of the polymers. This statistical sensitivity to the environment is well known in ordinary 3D solids, as is discussed later.

Several conditions are required for this study of polymers.

1. The polymers must be static, that is embedded in a solid, which must be a glass, so as not to strain their structure with respect to that in liquid solution. This constraint does not exist in standard SANS, because the high energy of the neutrons (by comparison with the kinetic energy of the atoms or molecules), the polymer motions in a liquid are completely unnoticed by them: for neutrons, a liquid is as 'static' as a solid.
2. Only the nuclei of the polymer must have a large nuclear moment, and not those of the solvent, to investigate the structure of the polymer itself, without contributing to relaxation from the solvent nuclei. The obvious choice is that of protonated polymers in a deuterated solvent. The latter must be a good solvent down to the glassy transition, so as to preserve the structure of the polymers and to avoid their segregation.
3. The only sufficiently tractable case is that when the paramagnetic centers are located on the polymer itself, and not in the solvent. For usual protonated polymers, the choice is most often limited to nitroso radicals. Furthermore, these radicals must be easily grafted to the polymers.
4. The electronic relaxation time, which in practice is the correlation time for the nuclear relaxation, must have an adequate value which imposes that the sample temperature be in the liquid nitrogen range.
5. In order for the time required for nuclear relaxation to remain within a reasonable range, it is necessary for the concentration of paramagnetic centers relative to the relaxing nuclei not to be too small. In the case when only one center is grafted on each polymer, this imposes in practice a maximum size for the polymers.

An experiment of diffusion-free nuclear relaxation by impurities on fractal systems has already been done. (This is the second exception to non-NMR studies to polymer-like fractal structure.) It was performed on ²⁹Si by Devreux et al. in silica aerogels.⁸ These have a network structure characterized by a fractal dimension D slightly in excess of two. Using an angular average for the individual relaxation rates, the authors showed that the initial variation of the nuclear polarization was proportional to $t^{D/6}$. This was tentatively extended to an exponential law of the form

$$\langle p(t) - p_{eq} \rangle \propto \exp \left[- \left(\frac{t}{\tau_1} \right)^{D/6} \right] \quad (1)$$

Experimentally, spin diffusion was quenched by averaging the dipole-dipole interactions between ²⁹Si nuclei to zero by

sample spinning at the magic angle $\theta = \arccos(1/\sqrt{3})$, and the results correlated well with theory.

In this article, diffusion-free relaxation is investigated in the absence of irradiation, or under off-resonance nuclear irradiation as a function of the angle between the effective field in the rotating frame and the steady field. The measurements concern both the rate of evolution of the bulk nuclear magnetization along the effective field and its steady-state limit. Two types of systems were studied: the paramagnetic centers are grafted at random positions on the polymer; or only one center is grafted on each polymer in a well defined position, usually at one end. For the results to be interpretable, the polymers are monodispersed.

The article is organized in the following sections:

1. A review of the basic facts of nuclear relaxation by dipolar coupling with paramagnetic centers.
2. Description of the experimental procedure and its validation in a 3D solid.
3. Statistical properties of linear polymers in dilute or semi-dilute solution, as results from theory backed by neutron scattering experiments.
4. Description of the investigation of several systems and comparison with theory.
5. Discussion of the problem of spin ‘diffusion’.
6. Conclusion and perspectives.

2 BASICS OF RELAXATION BY FIXED PARAMAGNETIC CENTERS

This section is essentially a short summary of well-known facts of NMR.

It has been known since 1949⁹ that in insulating solids, the relaxation of nuclear spins 1/2 proceeds from the combination of two processes: direct relaxation by paramagnetic centers, usually present at low concentration, combined with homogenization of the polarization throughout the sample via dipolar-induced flip-flops among the nuclear spins, described by a diffusion equation, leading to an exponential decay of the bulk polarization. The situation is changed when the flip-flops are quenched by a decrease of the effective dipolar interactions, for instance through a strong off-resonance rf irradiation so as to orient the effective field in the rotating frame at the magic angle from the external field.^{10–12} Then, one observes the independent direct relaxation of the individual spins. Even when the dipolar interactions are not completely averaged to zero, it is generally possible to observe the diffusion-free relaxation at the beginning of the nuclear magnetization evolution. These are the conditions used in the present study.

2.1 Nuclear Spins Subjected to Strong rf Irradiation

A system of nuclear spins I in a steady magnetic field is subjected to a strong rf field B_1 rotating at a frequency ω at a value $\Delta = \omega_0 - \omega$ from the Larmor frequency. In a frame rotating at frequency ω , the spins are subjected to a steady magnetic field B_{eff} of components $-\Delta/\gamma$ and B_1 along the axes Oz and Ox respectively, that is oriented along an axis OZ tilted by the angle $\theta = \arctan(B_1/(-\Delta/\gamma))$ Oz (see Figure 1). The effective Hamiltonian has the form

$$\mathcal{H}_{\text{eff}} = \Delta I_z + \omega_1 I_x + \mathcal{H}'_{Dz} = \Omega I_Z + \mathcal{H}'_{Dz} \quad (2)$$

Figure 1 Effective field in the rotating frame under off-resonance irradiation

where, in the last term on the right-hand side, we express the effective Zeeman interaction with respect to the orientation OZ of the effective field (see Figure 1), and $\mathcal{H}'_{Dz}$ is the secular dipolar interaction in the rotating frame, commuting with the operator I_z .

If as we assume, the effective Zeeman interaction is much larger than the dipolar one, the latter has to be truncated so as to retain only its part which commutes with the effective Zeeman interaction, that is with the spin operator I_z . This is done by rewriting the dipolar Hamiltonian in the system of axes $OXYZ$ and rejecting all terms which differ from $\mathcal{H}'_{Dz}$, of the same form as $\mathcal{H}'_{Dz}$ but expressed in the new system of axes. The corresponding coefficient is equal to $1/2(3 \cos^2 \theta - 1)$, a standard result recalled in Tabti et al. and discussed at length in Blumberg, Tse and Hartmann, and Lin and Hartmann.^{7,9–11} It is easily recovered by an elementary calculation. The new effective dipolar interaction is then

$$\mathcal{H}''_{Dz} = \frac{1}{2}(3 \cos^2 \theta - 1) \mathcal{H}'_{Dz} \quad (3)$$

The magnitude $1/2|3 \cos^2 \theta - 1|$ can be modified at will within limits by adjusting the angle θ . If we use a second rotating frame, of frequency Ω around OZ , the evolution of the spin system is governed by the effective dipolar interaction $\mathcal{H}''_{Dz}$.

2.2 Local Nuclear Relaxation by a Paramagnetic Center

We consider a paramagnetic spin S at the origin and a nuclear spin I with polar coordinates (r, α, β) . Under rf irradiation, the orientation of the spin I is locked along the

direction OZ of its effective field in the rotating frame. Its relaxation through its dipolar coupling with the spin S is calculated through a combination of the methods of Abragam and Tomita.^{13,14} The spin S components fluctuate randomly under the effect of its own spin-lattice relaxation, with a longitudinal time T_{1e} . We assume that $\omega_e T_{1e} \gg 1$, where ω_e is the electronic Larmor frequency, so that the only effective S spin component contributing to the nuclear relaxation is S_z , and the correlation time of the random $I - S$ coupling is $\tau_c = T_{1e}$. The relaxing Hamiltonian is of the form

$$\mathcal{H}_{IS}(t) = AS_z(t)I_z + \{BS_z(t)[I_x + iI_y] + h.c.\} \quad (4)$$

with

$$\begin{aligned} A &= \frac{\gamma_I \gamma_S \hbar}{r^6} (1 - 3 \cos^2 \alpha), \\ B &= -\frac{3}{2} \frac{\gamma_I \gamma_S \hbar}{r^6} \sin \alpha \cos \alpha \exp(-i\beta) \end{aligned} \quad (5)$$

In the hypothesis, often realistic, that $\Omega\tau_c \ll 1$, the relaxation evolution of the component I_Z is a weighted average of those of I_z and I_x . It corresponds to the equation

$$\frac{d}{dt} \langle I_Z \rangle = -\frac{1}{T_1} [\langle I_Z \rangle - \langle I_Z \rangle_{st}] \quad (6)$$

where a standard relaxation calculation yields

$$\frac{1}{T_1} = \frac{S(S+1)}{3} [A^2 \sin^2 \theta J(0) + 2|B|^2 (1 + \cos^2 \theta) J(\omega)] \quad (7)$$

The spectral densities are of the usual form

$$J(\omega) = \frac{\tau_c}{1 + \omega^2 \tau_c^2} \quad (8)$$

The relaxation rate, equation (7), can be written under the general form

$$\frac{1}{T_1}(\alpha, r) = \frac{C(\alpha)}{r^6} \quad (9)$$

where $C(\alpha)$, which depends on the angle α between the direction of the vector SI and the external field through the square of its sine or cosine, also depends on the angle θ between effective and external fields.

Equation (7) agrees with the relaxation rates derived for the z and x components

$$\frac{1}{T_{1z}} = \frac{1}{T_1}(\theta = 0); \quad \frac{1}{T_{1x}} = \frac{1}{T_1}(\theta = 90^\circ) \quad (10)$$

As for the steady-state value towards which $\langle I_Z \rangle$ evolves, it corresponds to a compromise between the tendency of $\langle I_z \rangle$ to evolve towards the thermal equilibrium value I_0 and that of $\langle I_x \rangle$ to evolve towards 0. The result is

$$\langle I_Z \rangle_{st} = I_0 \frac{\cos \theta}{\cos^2 \theta + (T_{1z}/T_{1x}) \sin^2 \theta} \quad (11)$$

All these results can be cleanly derived, and they can be extended to the case when the condition $\Omega\tau_c \ll 1$ is not fulfilled: one must simply replace $J(0)$ with $J(\Omega)$ in equation (7).¹⁵

2.3 The Steady-State Polarization in a Bulk Sample

The steady-state polarization for a single spin I given in equation (11) depends on the polar angle α through the dependence of T_{1z} and T_{1x} on this angle. In a bulk sample, flip-flop processes, when given enough time to take place, homogenize these steady-state values. The final result is a bulk steady-state polarization of the form

$$\frac{\langle I_Z \rangle_{st}}{I_0} = \frac{\cos \theta}{\cos^2 \theta + f(\tau_c) \sin^2 \theta}, \quad (12)$$

where the factor $f(\tau_c)$ is equal to a ratio of average relaxation rates

$$f(\tau_c) = \left(\frac{1}{T_{1x}} \right) / \left(\frac{1}{T_{1z}} \right) \quad (13)$$

Its formal expression is

$$f(\tau_c) = \frac{1}{2} + \frac{2}{3} \omega^2 \tau_c^2 \quad (14)$$

The importance of equations (12) and (14) is that by merely measuring the steady-state NMR signal as a function of the angle θ between effective and external field, one obtains an accurate determination of the correlation time τ_c , that is the spin-lattice relaxation time of the paramagnetic centers, irrespective of whether the EPR linewidth is homogeneous or inhomogeneously broadened. This very general result, independent of the structure of the system, may be considered a by-product of some value of the present study.

2.4 Diffusion-Free Relaxation in a Bulk Sample

We give here but an outline of the way of handling the problem of determining the shape of the relaxation evolution of the bulk polarization towards its steady-state value.

The problem is essentially of statistical nature. The magnetization of each individual nuclear spin evolves according to the equation

$$\langle I_Z^i \rangle(t) = \langle I_Z^i \rangle_{st} + (\langle I_Z^i \rangle(0) - \langle I_Z^i \rangle_{st}) \exp\left(-\frac{t}{T_1^i}\right) \quad (15)$$

One must sum over all spins, or else consider a 'typical' spin and calculate its average evolution through the probability distribution of relaxation times and steady-state limits

$$\langle I_Z \rangle(t) = \overline{\langle I_Z \rangle_{st}} + \overline{\langle I_Z \rangle(0) \exp\left(-\frac{t}{T_1}\right)} - \overline{\langle I_Z \rangle_{st} \exp\left(-\frac{t}{T_1}\right)} \quad (16)$$

Where the overbar means a bulk statistical average, whereas the brackets correspond as usual to quantum-mechanical expectation values.

As a general rule, all initial magnetizations are equal, which is why the second average on the right-hand side of equation (16) is only on the time-dependent term. This average is relatively easy to calculate. This is not the case for the last joint average, because both the individual $\langle I_Z^i \rangle_{st}$ and T_1^i produced by a single paramagnetic center depend on the polar angle α . This is not too severe when the paramagnetic centers are distributed at random, because most spins will be relaxed by several centers, and the local $\langle I_Z^i \rangle_{st}$ will not differ much from the average. The problem might arise in the case of dilute polymers with only one center grafted on each, that is when

all nuclear spins are relaxed only by one center. However, in all cases studied so far, one always had $\omega\tau_c \gg 1$, so that except in a very small domain of angles α around the magic value, one has $T_{1z}^i/T_{1x}^i \gg 1$ and $\langle I_Z^i \rangle_{st}$ is small compared with $\langle I_Z \rangle(0)$, so that its exact value is of little importance over most of the evolution.

The methods used for calculating the average $\overline{\exp(-t/T_1^i)}$ will not be detailed here, and we will only give and briefly comment on the results for the various cases under study.

3 THE MODEL STRUCTURE OF LINEAR POLYMERS

Although the experimental study was made with finite and relatively short polymers, we describe them by the same model as that derived theoretically in the limit of very long polymers.¹⁻³

Linear polymers in dilute solution, that is at a concentration c smaller than the overlap concentration c^* , to be defined later, are independent of each other. Being flexible, they can be present under a variety of configurations. One can define a mean statistical structure by performing an average of all possible configurations. This structure is of spherical symmetry and is characterized by a fractal dimension D . What is meant by this is that around any point of the polymer the number of monomers (or the number of nuclei) present in a sphere of radius r is of the form

$$n_n(r) = \lambda r^D \quad (17)$$

from which we can define an average nuclear density $\rho(r)$ through

$$\frac{d}{dr} n_n(r) = D\lambda r^{D-1} = 4\pi r^2 \rho(r) \quad (18)$$

that is

$$\rho(r) = \frac{1}{4\pi} D\lambda r^{D-3} \quad (19)$$

For linear polymers in solution in a good solvent, this dimension is equal to $D = 1.7$.

We define an effective radius R as that of a sphere that contains all the nuclei N_n of the polymer

$$R = \left(\frac{N_n}{\lambda} \right)^{1/D} \quad (20)$$

and we assume that the density $\rho(r)$ is of the form shown in equation (19) up to $r = R$ and vanishes at larger values. This is obviously an oversimplification, but it will turn out to be convenient.

Among other kinds of radii used in the study of polymers there is the so-called gyration radius R_G defined through

$$R_G^2 = \frac{1}{2(N+1)^2} \sum_{i,j} (\mathbf{r}_i - \mathbf{r}_j)^2 \quad (21)$$

where N is the number of monomers and $\mathbf{r}_i - \mathbf{r}_j$ is the vector joining the monomers i and j . Its value is experimentally derived by small angle neutron scattering.

Another radius, called R_F , equal to the r.m.s. end-to-end distance of the polymer, is theoretically related to R_G through

$R_F = 2.51 R_G$. The vector R of equation (20) is likely to be of an order of magnitude that is similar to these radii.

Among several different definitions of the polymer overlap concentration c^* , the simplest one in the present case is

$$4\pi R^3 c^* = 1 \quad (22)$$

The polymers are said to be in semi-dilute solution when their concentration c is somewhat larger than the concentration c^* , so that they partly overlap. In this case, all points of the polymer are still statistically equivalent: in a sphere of radius ξ around a 'typical' point, the fractal dimension has the same value $D = 1.7$ as in dilute solution, and beyond this distance, the dimension is the same as that of the host medium, that is $D = d = 3$.

The knowledge of the fractal dimension is sufficient to determine the shape of the signal evolution at short time, when only those nuclei close to a paramagnetic center are substantially relaxed. The centers are at low concentration, so that these nuclei are only relaxed by one impurity. The centers being grafted on the polymers, the density of nuclei around them corresponds to the same fractal dimension as the polymers. Starting from zero initial saturation, the evolution of the nuclei at a polar angle α with respect to the center is approximately of the form

$$\langle I_Z \rangle(\alpha; t) \propto \langle I_Z \rangle_{st} \int_{r=b_0}^{\infty} \left[1 - \exp\left(\frac{-C(\alpha)t}{r^6}\right) \right] d(r^D) \quad (23)$$

where b_0 is the barrier within which the nuclei, of frequency shifted by the average electronic dipolar field, are not observed. For $ct/b_0^6 \gg 1$, and by using the notation

$$x = \frac{C(\alpha)t}{r^6} \quad (24)$$

we obtain a result of the form

$$\langle I_Z \rangle(\alpha; t) = \langle I_Z \rangle_{st} (1 - \zeta t^{D/6}) \quad (25)$$

This form remains true when integrating over the angle α . As for the complete form of the evolution, it requires a more elaborate calculation, and it depends on the distribution of the relaxing centers around the nuclei.

4 EXPERIMENTAL METHODS – VALIDATION ON A 3-D SYSTEM

4.1 Experimental Procedure

Within an electromagnet producing a horizontal field, the sample is cooled in a cryostat by flowing cooled nitrogen gas around it. A resistor is used to adjust the gas temperature to within 0.5 K between liquid nitrogen and room temperatures. The sample temperature was as a rule around 100 K. The pulsed spectrometer operates at a frequency around 100 MHz. The field B_1 is of the order of 1 mT, rotating component, that is much larger than the local field of the compounds used, about 0.2 to 0.3 mT. The rf field can be applied up to 9 s without problems.

The measuring sequence goes as follows: the thermal equilibrium magnetization is spin-locked along the direction OZ of the effective field; after an evolution time t , the

magnetization is as a rule realigned with the steady field and then subjected to a $\pi/2$ pulse, and the FID amplitude is measured. The manipulations of the magnetization directions are performed by appropriate pulses and evolution periods.

4.2 Validation on a 3-D Solid: Protonated *O*-Terphenyl

The sample was protonated *o*-terphenyl (OTP) doped with the radical 4-hydroxyl TEMPO (tetramethyl-2,2,6,6 piperidinol-4 oxyle-1) at a concentration of $4.3 \times 10^{19} \text{ cm}^{-3}$. It was degassed and cooled at 143 K. The centers were then randomly distributed. The relaxation time without rf irradiation was 0.78 s.

For randomly distributed relaxing centers, the theoretical evolution of the nuclear magnetization is an exponential function of $\sqrt{t}$, in accordance with the initial law (see equation (25)).^{6,7,10-12,16}

$$\langle I_Z \rangle(t) - \langle I_Z \rangle_{st} = (\langle I_Z \rangle(0) - \langle I_Z \rangle_{st}) \exp \left[- \left(\frac{t}{\tau_1} \right)^{1/2} \right] \quad (26)$$

This law is deduced from a statistical analysis of the paramagnetic center random distribution, and from the fact that, when 'seeing' several paramagnetic centers, the relaxation rate of a given nucleus is the sum of those due to the individual centers.

The expressions for the relaxation rates and steady-state magnetizations as a function of the angle θ between external and effective fields are given in Tabti and Tabti et al. with only two adjustable parameters: the correlation time $\tau_c = T_{1c}$ and the concentration of the relaxing centers. The variation of the steady-state reduced magnetization as a function of the angle θ is shown in Figure 2, together with a best-fit theoretical curve corresponding to

$$\tau_c = 6.5 \pm 0.2 \times 10^{-8} \text{ s}. \quad (27)$$

Figure 2 Reduced steady-state magnetization as a function of the angle θ between external and effective field in protonated OTP, together with a best-fit theoretical curve with $\tau_c = 6.5 \pm 0.2 \times 10^{-8} \text{ s}$

As for the time-decaying part, it consists of three parts: an initial plateau due to the non-observation of the nuclei close to the centers, an exponential function of $\sqrt{t}$ of the form shown in equation (26), and a final exponential decay as a function of t , when spin diffusion becomes faster than direct relaxation. For the part evolving according to equation (26), the variation of $\tau_{1/2}$ as a function of the angle θ is shown in Figure 3 together with a best-fit curve.

Using the preceding value of τ_c , it yields the concentration of paramagnetic centers

$$N_p = 6.4 \pm 0.1 \times 10^{19} \text{ cm}^{-3} \quad (28)$$

The fact that this concentration is larger than the nominal one is attributed to the evaporation of some OTP during the degassing process.

These results constitute a validation of the experimental procedure, and provide in addition two pieces of information: the electronic relaxation time and the concentration of the centers.

5 RESULTS FOR POLYMER SOLUTIONS

5.1 Polymers with Randomly Distributed Paramagnetic Centers

The only system studied consisted of poly 2-vinyl pyridine (P_2VP) of average molecular mass $2 \times 10^5 \text{ g mole}^{-1}$ on which paramagnetic vanadyl sulphate $VOSO_4$ was grafted at random. It was in semi-dilute solution ($c = 0.05 \text{ g cm}^{-3}$) in deuterated glycerol. This system, studied only for illustration purposes, did not use rf irradiation, and it concerns only the longitudinal relaxation.

For polymers of fractal dimension D with random relaxing centers grafted on them, a statistical calculation analogous to that use for 3-D solids yields an evolution law of the magnetization of the form

$$\langle I_Z \rangle(t) - \langle I_Z \rangle_{st} = (\langle I_Z \rangle(0) - \langle I_Z \rangle_{st}) \exp \left[- \left(\frac{t}{\tau_1} \right)^{D/6} \right] \quad (29)$$

Figure 3 Variation of $\tau_1^{1/2}$ as a function of the angle θ in protonated OTP, together with a best-fit curve with $N_p = 6.4 \pm 0.1 \times 10^{19} \text{ cm}^{-3}$

Figure 4 Longitudinal relaxation curve for a semi-dilute solution of P₂VP. The initial decay, an exponential function of $t^{D/6} = t^{0.28}$ (solid line), is followed by an exponential function of time (dashed curve)

The experimental magnetization evolution, shown in Figure 4, does indeed display such an initial behavior, followed at longer times by an exponential variation, when spin diffusion takes over.

5.2 Polymers with One Paramagnetic Center at One End

The situation for relaxation is markedly different from the preceding one. Indeed, for dilute solution, the relaxation of the nuclei of a polymer is essentially produced by only one center, the one located on the polymer. What the statistical calculation predicts is that over a substantial range, the evolution of the magnetization is a *linear* function of $t^{D/6}$

$$\langle I_Z \rangle(t) - \langle I_Z \rangle_{st} = (\langle I_Z \rangle(0) - \langle I_Z \rangle_{st}) \left(1 - \left(\frac{t}{\tau_1} \right)^{D/6} \right) \quad (30)$$

The theoretical curve for the model used is shown in Figure 5, together with an exponential of equal initial slope for comparison. The expected variation for the polymer is indeed linear from initial value 1 down to about 0.4–0.3. We come now to the experimental investigation.

The polymer used is polystyrene of molecular mass of about 8000 (i.e., corresponding to 80 monomers) at the end of which was grafted the radical tetramethyl-2,2,5,5 carboxy-3 pyrrolinyl oxyle-1 (commercial name 3-carboxy PROXYL), diluted in deuterated OTP and then cooled to 120 K. The overlap concentration c^* is estimated to about 0.25 g cm^{-3} . Experiments were performed on dilute and semi-dilute solutions.

From a study of the steady-state reduced polarization as a function of the angle θ , shown in Figure 6, the best-fit value for the correlation time is

$$\tau_c = 2.6 \pm 0.4 \times 10^{-8} \text{ s}. \quad (31)$$

Figure 5 Theoretical variation of the reduced magnetization as a function of $t^{0.28}$ in a dilute solution of polymers with one relaxation center at one end (solid curve). For comparison, the dashed curve is an exponential with the same initial slope

Figure 6 Dilute solution of polystyrene with one relaxing center at one end. Reduced steady-state magnetization as a function of the angle θ , together with a best-fit theoretical curve with $\tau_c = 2.5 \pm 0.4 \times 10^{-8} \text{ s}$

5.2.1 Dilute Solution

The polystyrene concentration was 0.05 g cm^{-3} . A typical evolution curve, for the magic angle $\theta = \arccos(1/\sqrt{3})$, is shown in Figure 7.

One observes indeed a linear variation, but down to about 0.1, that is beyond theoretical expectation. This may be due to the crude structure model used: a sudden drop of the nuclear concentration beyond R , or to the interaction with the other polymers. In the absence of any firm theoretical model for the concentration variation of the nuclear density at the largest

Figure 7 Dilute solution of polystyrene with one relaxing center at one end. Relaxation along an effective field at the magic angle from the external field. Linear reduced magnetization as a function of $t^{0.28}$

Figure 8 Semi-dilute solution of polystyrene with one relaxing center at one end, under irradiation at resonance. Linear reduced magnetization as a function of $t^{0.28}$

distances, we did not investigate this matter further. Knowing τ_c from the steady-state variation, it is possible to determine the radius R from the evolution with angle θ of the value of τ_1 in equation (30). The best fit value is:

$$R = 3.1 \pm 0.15 \text{ nm}, \quad (32)$$

to be compared with the neutron-scattering-measured value $R_G = 2.1 \text{ nm}$ and the corresponding $R_F = 5.2 \text{ nm}$. All three radii are indeed of the same order of magnitude.

5.2.2 Semi-dilute Solution

The same polystyrene polymers were used at a concentration of 0.30 g cm^{-3} , slightly above the overlap concentration $c^* = 0.25 \text{ g cm}^{-3}$. The experimental relaxation evolution is shown in Figures 8 and 9 for $\theta = 90^\circ$. In Figure 8, the signal is plotted as a function of $t^{D/6}$ and it exhibits the same linear variation as for the dilute solution. In Figure 9, the signal is plotted as a function of $t^{1/2}$ on a logarithmic scale, showing that in the end the signal varies as an exponential function of $\sqrt{t}$. All these features agree qualitatively with the model of semi-dilute solutions of polymers: a region of fractal dimension 1.7 with at most one impurity, surrounded by a homogeneous medium with randomly distributed paramagnetic centers.

6 THE PROBLEM OF SPIN DIFFUSION

This topic, which is not directly connected with the NMR investigation of the polymer structure, will be given a schematic discussion only.

When the angle between the effective and external fields is different from the magic angle, i.e., when the effective secular dipolar interactions do not vanish, the end of evolution of the signal is an exponential function of time. This is brought

Figure 9 Same as Figure 8, but with different scales: Logarithm of the reduced magnetization as a function of $t^{1/2}$ (solid line), and its variation as a function of $t^{0.28}$ (dashed curve)

about by the homogenization of the polarization through flip-flop processes under the influence of the secular dipole-dipole interactions. In usual 3-D solids, this nuclear polarization transfer through space is tentatively described by a diffusion equation, and referred to as spin diffusion. All experimental results on nuclear relaxation by paramagnetic centers in non-conducting solids are in good agreement with this description.

Besides more or less complicated and approximate theoretical treatments of this problem, a particularly enlightening picture of spin-diffusion-induced exponential evolution is that of Blumberg. We summarize it for the so-called diffusion-limited case, in a spherical system of radius R with a relaxing center at the origin, and neglect the angular dependence of the

coefficient C , in equation (9), as well as that of the diffusion coefficient D . The time necessary for direct relaxation to reach the distance r is of the order of $t_r = r^6/C$, whereas the corresponding time for diffusion is of the order of $t_d = r^2/D$. Both times are equal at a distance

$$b \approx \left(\frac{C}{D}\right)^{1/4} \quad (33)$$

Up to this distance, relaxation acts independently on the nuclei, and beyond it diffusion homogenizes the polarization. The relaxation of this part is exponential, with a relaxation rate equal to the average of the individual rates. If ρ is the nuclear density, we obtain

$$\frac{1}{T_1} \approx \frac{C \int_b^R \rho r^{-4} dr}{\int_b^R \rho r^2 dr} \quad (34)$$

which, for a 3-D solid where the density is constant and for $b \ll R$, yields

$$\frac{1}{T_1} \approx \frac{C}{R^3 b^3} \quad (35)$$

a result equal, within a numerical factor of order unity, to that predicted by more sophisticated methods, and in agreement with experiment for randomly distributed centers at low concentration, with R equal to the average distance between centers. We can compare it with the time τ necessary for diffusion to travel the distance R

$$\tau \approx \frac{R^2}{D} \quad (36)$$

We obtain from equations (33) and (35)

$$\frac{\tau}{T_1} \approx \frac{(C/D)R^2}{R^3 b^3} \approx \frac{b}{R} \ll 1 \quad (37)$$

which validates the coherence of the model.

This approach is not adapted to dilute polymers of fractal dimension $D = 1.7$, for two reasons. First, and contrary to direct relaxation, it is hardly justified to use an ‘average’ polymer, since the dipolar-induced transport of polarization is likely to depend critically on the spatial structure of each polymer. In particular, linear polymers make loops, and there is at present no clean theory of the relative importance of polarization transport along the polymer and through monomers well separated in the linear polymer but accidentally close in space. It is even not known whether this transport can be described by a diffusion equation, nor if the average square distance over which polarization is transported is proportional to time. The second reason why the Blumberg approach fails is that it would yield unphysical predictions even if we could use an average polymer structure and a diffusion equation. We see this briefly. Let us assume that in a polymer both equations (33) and (34) are valid. With a density $\rho \propto r^{D-3}$, we obtain for $b \ll R$, and after a little algebra

$$\frac{1}{T_1} \approx \frac{C}{R^D b^{6-D}} \text{ and } \frac{\tau}{T_1} \approx \left(\frac{b}{R}\right)^{D-2} \quad (38)$$

For $D < 2$, the last ratio is larger than unity! This is in contradiction with the hypotheses of the model. The conclusion is that for a system of low dimensionality, diffusion can take over direct relaxation only at distance substantially larger than b as given by equation (33). This conclusion is confirmed by the experimental results on dilute and semi-dilute solutions of polystyrene. As an example, for an angle $\theta = 25^\circ$ between effective and external fields in a dilute solution of polystyrene, the exponential part of the signal corresponds approximately to 30 per cent of the total signal. The distance r_1 beyond which the polarization is homogenized by diffusion corresponds to $(r_1/R)^D \simeq 0.7$ that is $(r_1/R \simeq 0.8)$. We use this value in equation (34), with the integrations between r_1 and R for calculating T_1 . As for the diffusion time, it has to be taken from r_1 to R : $\tau \approx (R - r_1)^2/D$. We obtain finally, with the help of equation (33)

$$\frac{\tau}{T_1} \approx 0.03 \left(\frac{b}{R}\right)^4 \ll 1, \quad (39)$$

which lifts the inconsistency.

It would be pointless to extend the discussion further, both because of the doubtful validity of a spin diffusion equation for a collection of polymers and because it is at distances close to R that the model for the variation of the nuclear density with distance should cease to be strictly valid.

7 CONCLUSION AND PERSPECTIVES

The study of direct spin-lattice relaxation of polymers by fixed paramagnetic centers grafted on the polymers turns out to be indeed a useful complement to their investigation by small angle neutron scattering, in particular for confirming their fractal structure. At the present experimental stage, it cannot be claimed that NMR by itself can actually determine the fractal dimension with great accuracy, but it confirms the findings of SANS from a very different type of approach.

However, NMR has potential capabilities that might go beyond those of SANS. An example provided by the experiments on dilute solutions of polystyrene is the shape of the relaxation decay, distinctly different in its last part from theoretical expectation, which hints at the possibility of refining the form of nuclear density near the edge of the polymer. We list a number of openings for which NMR could equally well provide information essentially unavailable by other means:

- placing the paramagnetic centers in the solvent rather than on the polymers, which could provide information on the space excluded by the presence of the polymers and its shape.
- use of a polycrystalline host in order to reveal whether this has an influence on the polymer shape. This possibility is forbidden to SANS, since the grain boundaries would cause a neutron scattering far larger than that due to the polymers.
- use of partly deuterated polymers, so as to have access to the position of given parts of the polymer relative to the end where the relaxing center is grafted.
- consider other polymer configurations. A general but still preliminary study has in fact been made on the relaxation characteristics of polymers close to a surface where paramagnetic centers are located, either grafted to the surface

or adsorbed by the surface, as a function of the surface density of the polymers with respect to their length.¹⁶ This study also envisioned the interest of using partly deuterated polymers.

1 INTRODUCTION

One of the key goals of materials science is the establishment of structure–property relationships in order to improve known and design new materials. This holds in particular for synthetic polymers, whose properties depend on both the molecular structure and the organization of the macromolecules in the solid state: their phase structure, morphology, molecular order and molecular dynamics.^{1,2} Macroscopic as well as microscopic parameters are influenced by processing that follows the chemical synthesis. This calls for powerful analytical tools that can probe these aspects in the material as it is used, predominantly in the solid state. The structural aspects are studied mostly by scattering techniques or by microscopy. Information about dynamic aspects are deduced mainly from scattering or relaxation experiments.³ Among these, nuclear magnetic resonance^{4,5} is well established in structural characterization of liquids or compounds in solution; however, this is much less the case for solids.^{6,7} Moreover, NMR offers numerous ways to study dynamic aspects over a large range of characteristic rates. The main advantage of NMR is its unprecedented selectivity. Thus, it is desirable to exploit this technique for studying the structure and dynamics of solid polymers.^{7,8} However, owing to the presence of angular-dependent anisotropic interactions, the spectral resolution of solid state NMR spectra is orders of magnitude lower than that of high-resolution NMR in liquids. Important improvements were achieved in the 1970s by combining high-speed mechanical rotation of the sample with ingenious manipulations of the nuclear spins, such as multiple pulse irradiation, high-power decoupling and cross polarization.⁹ Moreover, two- and higher-dimensional NMR techniques have been introduced that offer fundamental advantages.¹⁰ First, as in liquids, the introduction of a new frequency dimension provides a means to increase the spectral resolution. Even more importantly, multidimensional spectroscopy also provides routes to new information, unavailable from 1D spectra even in the limit of high resolution. Experiments can be designed that correlate different spin interactions providing

different structural information, or relate various states taken up by the molecular unit during different time periods by exchange, and in this way they can probe dynamic processes in real time.

Progress in multidimensional solid state NMR has been hampered by experimental and conceptual difficulties, which have now been overcome.^{11–14} This article briefly outlines some of the main concepts and illustrates the information available from multidimensional solid state NMR spectra about polymer structure and dynamics through selected experimental examples, mainly from the author's laboratory.

Polymer dynamics is of central interest in our studies. Of the great variety of molecular motions possible in polymers (e.g., translations, rotations, and vibrations), rotations have the most pronounced effects on NMR lineshapes and relaxation parameters. Thus, multidimensional NMR provides, in particular, unique information about rotational motions. Their timescales are followed in real time over many orders of magnitude, covering in particular the regime of slow motions, which govern the mechanical properties of polymers. Moreover, the higher-order correlation functions provided by multidimensional NMR yield previously inaccessible model-independent information about the geometry of rotational motions, the orientational memory of molecular units involved in complex dynamics, and the nature of nonexponential relaxation in disordered systems. This information collected for a variety of polymers should eventually lead to a better understanding of their mechanical and rheological behavior, which is of interest not only for conventional but also for new advanced polymeric materials.

Two other aspects are particularly important for establishing structure–property relationships for polymer materials, namely, chain alignment in partially ordered systems and domain sizes in heterogeneous polymer materials. The orientation of macromolecular units is used to improve the properties of polymers for such different applications as high-tensile-strength fibres and nonlinear optical materials for information technology. Advanced polymer materials almost inevitably consist of more than one component, which often leads to phase separation. Careful design of the molar ratios as well as the size, composition, and morphology of the different phases offers a means to control the mechanical, electrical, and optical properties. Small domains that extend over only a few nanometers, as well as interfacial regions between the different phases, are particularly difficult to characterize. Major advances have been achieved in these areas by introducing the concepts of multidimensional spectroscopy. The new solid state NMR techniques nicely supplement well-established scattering and microscopic methods, as demonstrated by various experimental examples and by explicit comparison.

2 SOLID STATE NMR

The various aspects of solid state NMR are treated in detail in other articles in this Encyclopedia. Therefore, only a brief outline of the techniques used in the applications described below are given here. A full treatment is also available in our extended monograph on solid state NMR and polymers.¹⁴

2.1 One-Dimensional NMR

Solid state NMR exploits anisotropic, angular-dependent interactions of nuclear spins with their surroundings,^{4,5} in particular magnetic dipole–dipole coupling of nuclei among themselves. This leads to broad NMR lines covering approximately 50 kHz for ^1H – ^1H homonuclear coupling and approximately 25 kHz for ^1H – ^{13}C heteronuclear coupling. The anisotropy of the chemical shift results in powder patterns covering approximately 15 kHz at a field strength of 7 T. In addition to these magnetic interactions, nuclei with spin $I > \frac{1}{2}$ can also have electric quadrupole moments and are subject to quadrupole coupling to the electric field gradient at the nuclear site. For ^2H ($I = 1$) in C– ^2H bonds, it leads to spectral splittings of about 250 kHz. Since C–H bonds are common in polymers, ^2H labeling is particularly useful.

If one of the above mentioned couplings dominates, either because of its strength or because the others have been suppressed by decoupling, the angular dependence of the NMR frequency in high magnetic fields is alike for all couplings, and is given by

$$\omega = \omega_L + \frac{1}{2}\Delta(3\cos^2\theta - 1 - \eta\sin^2\theta\cos 2\phi) \quad (1)$$

Here ω_L is the Larmor frequency, Δ describes the strength of the anisotropic coupling (i.e., the anisotropic chemical shift or ^{13}C – ^1H dipole–dipole coupling for ^{13}C or the quadrupole coupling for ^2H), and η is the asymmetry parameter describing the deviation of the anisotropic coupling from axial symmetry ($0 \leq \eta \leq 1$). The angles θ and ϕ are the polar angles of the magnetic field $\mathbf{B}_0$ in the principal axis system of the coupling tensor. This in turn is often simply related to the molecular geometry, with the unique axis lying along a bond direction (e.g., for dipole–dipole coupling along the ^{13}C – ^1H bond, and for quadrupole coupling along the C– ^2H bond), or perpendicular to an sp^2 plane as for ^{13}C chemical shift tensors in aromatic rings, etc. Depending on the total spin involved, signals described by equation (1) and their mirror images with respect to ω_L may be superimposed, and in powder samples spectra for all orientations are added to yield the powder lineshape (e.g., the Pake pattern for ^2H with spin $I = 1$).

These anisotropic interactions can be removed under rapid magic angle spinning (MAS), yielding liquid-like spectra if the spinning frequency ω_R is significantly larger than the width of the anisotropic powder pattern ($\omega_R \gg \Delta$). In the slow-spinning regime, $\omega_R < \Delta$, the centerband in the isotropic chemical shift is flanked by sidebands at multiples of ω_R , thus retaining information about the anisotropic coupling.

A few examples of 1D NMR spectra are collected in Figure 1, displaying single ^{13}C lines at the isotropic chemical shifts [Figure 1(a)], a chemical shift powder pattern for ^{13}C in a carboxyl group and its relation to the molecular geometry [Figure 1(b)], a ^{13}C MAS sideband pattern [Figure 1(c)], and ^2H NMR lineshapes for an isotropic powder [Pake pattern, Figure 1(d)], a uniaxially drawn fiber [Figure 1(e)], and a phenyl ring with motional averaging due to flipping about the axis shown [Figure 1(f)].

2.2 Two-Dimensional NMR

A 2D NMR spectrum is generated by recording a two-dimensional data set following pulsed irradiation as a function

Figure 1 Examples of solid state NMR spectra: (a) ^{13}C CP MAS spectrum displaying isotropic chemical shifts of different functional groups; (b) ^{13}C powder pattern for carboxyl group, governed by chemical shift anisotropy and relationship of the principal axes system of the shielding tensor to the molecular framework; (c) ^{13}C sidebands due to anisotropic chemical shift and slow MAS; (d) ^2H NMR lineshape for rigid isotropic powder (Pake pattern); (e) ^2H NMR lineshape for a uniaxial fiber; (f) ^2H NMR lineshape for flipping phenyl rings

of two time variables, as shown schematically in Figure 2(a), and subsequent double Fourier transformation. The development of the nuclear spin system in the evolution period with incremented time t_1 at the beginning of the pulse sequence provides the basis for the first frequency dimension ω_1 . The NMR signal is detected in the detection period with time t_2 at the end of the pulse sequence, providing the basis for the second frequency dimension ω_2 . In the exchange experiments described here, a variable mixing period of duration t_m , during which dynamic processes can take place, is inserted between evolution and detection. In this way, slow molecular dynamics are probed in real time. The concept of 2D spectroscopy is readily extended to three and higher dimensions by inserting additional evolution and mixing times.

The most important aspects of 2D NMR are exemplified in Figure 2(b)–(d). First, 2D NMR is often used to increase the spectral resolution of solid state NMR spectra by separating different interactions. As an example, consider 1D sideband patterns. These are often hampered by a severe loss of spectral resolution due to overlapping sidebands of ^{13}C with different isotropic chemical shifts. This loss of resolution is circumvented at the expense of a new frequency dimension, as demonstrated in Figure 2(b), where the sideband patterns for the different sites experiencing different isotropic chemical shifts are separated from each other.

Other 2D NMR techniques aim at obtaining new information by correlating different interactions. As a specific example, Figure 2(c) displays a 2D NMR spectrum correlating a ^{13}C chemical shift with a ^{13}C – ^1H dipolar powder

Figure 2 Principles of 2D NMR spectroscopy: (a) basic pulse sequence; (b) separation of isotropic and anisotropic chemical shifts; (c) correlation of anisotropic chemical shift and dipolar interaction; (d) 2D exchange spectrum reflecting the reorientation about the angle β through an elliptical exchange ridge

pattern. Since the dipole–dipole coupling is well understood in terms of bond lengths and angles, such spectra provide valuable information about the orientation of the principal axes of the chemical shift tensor in relation to structural units such as CH_2 – groups etc.

As far as applications to polymers are concerned, 2D exchange NMR has proved to be particularly valuable. First of all, by varying the mixing time t_m , slow dynamic processes in the range of milliseconds to seconds can be followed in real time. Moreover, 2D exchange NMR spectra yield unique and model-independent information about the geometry of rotational motions. In fact, for axially symmetric tensors, ubiquitous in ^2H NMR of polymers, the 2D exchange spectrum yields elliptical ridge patterns from which the angle about which the molecules have rotated can be read off with a ruler [Figure 2(d)].

2.3 Multidimensional NMR

The concepts of 2D NMR are readily extended to higher dimensions. By combining the different schemes of 2D NMR, a large variety of three-dimensional experiments can be designed, as discussed, for example, for liquid state NMR by Griesinger et al.¹⁵ In liquid state NMR, 3D techniques are mainly used to increase the spectral resolution. Although this is also an important aspect in solid state NMR (see below), 3D exchange NMR as shown schematically in Figure 3 offers fundamentally new information about higher-order correlation functions of complex motions in the solid state. Since the orientation of a given molecule is probed three times, different pathways taken by the molecule from the beginning to the end lead to different exchange signals. Thus, different motional mechanisms may be distinguished. Such information is inaccessible from 2D NMR, where the orientation of the molecule is measured only twice, and therefore no information is available about the trajectory a molecule follows when rotating from one orientation to another. Specific examples of applying three- and higher-dimensional NMR techniques to polymers are discussed below.

Figure 3 Principle of 3D exchange NMR: (a) pulse sequence; (b) corresponding spectral cube

2.4 Spin Diffusion

Solid state NMR can also provide information about intermolecular distances and domain sizes in heterogeneous polymers by means of spin diffusion, i.e., the diffusion of nuclear magnetization through the sample without transport of material. It is mediated by dipolar couplings, and therefore is most efficient among protons.⁴ Figure 4 demonstrates schematically the connection between the spatial distribution of proton magnetization within the sample and the solid state NMR spectra for a two-phase system with spatially constant proton density. In equilibrium, the proton polarization is spatially constant, and the relative signal intensities in an NMR spectrum reflect the integral chemical composition of the sample. Differences in the chemical structure or in local molecular mobility can be used to select the proton magnetization in one component (A) and suppress it in the other (B) [Figure 4(a)]. The subsequent redistribution of magnetization by ^1H spin diffusion is monitored by NMR spectroscopy [Figure 4(b)]. For short times, the mean-square distance $\langle x^2 \rangle$ that the magnetization moves within time t is given by $\langle x^2 \rangle = aDt$, where D is the spin diffusion constant of the system under study. The factor a depends on the geometry of the packing (e.g., lamellar, cylindrical, or spherical). The spin diffusion constant D is related to the strength of the dipolar coupling as reflected in the width of the ^1H NMR

Figure 4 Schematic representation of ^1H spin diffusion in a two-phase system (A,B) with spatially constant proton density: (a) spatial distribution of ^1H magnetization; (b) NMR spectra for different mixing times t_m

spectrum, and has been calibrated for polymers of different molecular mobility by comparing spin diffusion data with direct measurements of domain sizes by X-ray scattering and electron microscopy.^{16,17}

3 APPLICATIONS

3.1 Conformational Structure

The packing behavior of polymers depends strongly on their chain microstructure.¹⁸ In particular, it is well known that only stereoregular macromolecules can crystallize. A schematic representation of the carbon backbone of an amorphous polymer is depicted in Figure 5(a). In order to specify the conformation of such a segment, one must know the bond length l , the valence angle Θ and the rotational angles Φ_i . The rotational potential $E(\Phi_i)$ around the central C–C bond in *n*-butane is plotted in Figure 5(b). The minima for the *gauche* conformers are higher than that of the *trans* by about 3.5 kJ mol⁻¹. Since this energy difference is comparable to the thermal energy at ambient temperatures, a large number of

conformations is normally present in an amorphous polymer. Therefore, experimental techniques are needed that can check the conformational statistics.

NMR of polymers in solution is well established for determining the chain microstructure.^{6,19} Glassy solid state amorphous polymers typically display broad ¹³C cross polarization magic angle spinning (CP MAS) NMR lines due to an inhomogeneous superposition of contributions from different conformations. These conformational effects on ¹³C chemical shift have traditionally been attributed to the shielding of a reference carbon C⁰ by the γ -substituent C γ [see Figure 5(b)] in a semiempirical fashion ('the γ -*gauche* effect').^{6,8,19} It has been shown that these shifts can be calculated quantitatively on the ab initio level²⁰ by exploiting the high computing power of modern workstations and advanced schemes for calculating NMR chemical shifts, such as *individual gauge for localized orbitals* (IGLO).²¹ Thus, it is hoped that eventually the spread in chemical ¹³C shifts in amorphous polymers can be analyzed to provide structural information, in particular because profound correlations of the chemical shift with specific geometrical aspects such as C–C bond lengths and dihedral angles emerge.

As a specific example, Figure 6(a) displays the ¹³C CP MAS spectrum of atactic polypropylene (aPP), with the assignment of the two partially resolved peaks and the shoulder corresponding to specific conformations of a tetrameric unit depicted in Figure 6(b). The assignment is readily made by comparison with the chemically shifted peak positions of the solid state ¹³C NMR spectra of crystalline isotactic²² and syndiotactic polypropylene.²³ In the glassy state, the peaks are broadened owing to differences in the geometry²⁰ and to the fact that numerous configurations contribute to the three main conformations, as discussed in detail elsewhere.²⁴

Figure 5 (a) Schematic representation of a carbon-backbone polymer chain in the amorphous state. (b) The potential energy E for rotation about the central carbon of a butane unit in a polymer chain together with Newman projections illustrating the different interactions between the atom C⁰ and its γ -*gauche* substituent C γ for the conformations *gauche*– (g–), *trans* (t) and *gauche*+ (g+)

3.2 Molecular Order

Structural characterization of polymers often requires the determination of the alignment of macromolecular chains.²⁵ Orientation in polymers is often induced by the production process, and has strong effects on product properties. Through the angular-dependent NMR interactions, orientation is amenable to NMR experiments. As opposed to most classical techniques, the order of both crystalline and amorphous components can be studied. For ²H- or ¹³C-enriched samples, one-dimensional experiments are sufficient to obtain orientation distributions in terms of a single angle.²⁶ In order to reconstruct two-dimensional orientation distributions, or to resolve overlapping patterns in natural abundance ¹³C spectra, multidimensional spectra are required. Two examples are discussed here. Both involve 3D spectra of ¹³C in natural abundance.

3.2.1 Chain Alignment in Drawn Poly(ethylene terephthalate)

In the case of a biaxially drawn film of poly(ethylene terephthalate) (PET) from an industrial process line, the orientational distribution was mapped out in the 3D exchange NMR spectrum by flipping the sample between different orientations with respect to the magnetic field (*direction exchange with correlation for orientation distribution evaluation and reconstruction*, DECODER).²⁷ The NMR signals of the different structural units of PET are completely resolved in the

Figure 6 (a) ^{13}C CP MAS NMR spectrum of an amorphous polypropylene at $T = 252\text{ K}$ ($T_g - 6\text{ K}$).²⁴ Note that the observed splitting is due to conformational effects. (b) Schematic representation of the conformations of a tetrameric unit in polypropylene relevant for the γ -gauche effect of the methylene group C^0H_2 . One particular configuration, the mrr tetrad, is selected, here. The abbreviation $t^*.g$ stands for a conformational unit around a carbon center denoted by $\cdot$, with undefined conformations of the neighboring bonds and t and g conformations of the next-neighboring bonds

3D cube, and their orientation distributions thus separately determined.²⁸ As depicted in Figure 7(b), the chain axes are confined to the film plane (full-width at half-maximum, fwhm, of 15°), while the in-plane distribution is much broader (fwhm $\approx 90^\circ$). The planes containing the phenylene rings and the carboxyl group are oriented preferentially parallel to the plane of the film (fwhm = 55°).

3.2.2 Molecular Order in Liquid Crystalline Polymers

New polymeric materials often contain mesogenic groups that are able to form liquid crystalline phases.^{29,30} The interest in such liquid crystalline polymers (LCPs) comes from the fact that in the liquid crystalline phase, they can be macroscopically oriented not only by electric or magnetic fields but also by mechanical forces. The order thus generated in the mesophase can subsequently be retained in the solid material. This offers interesting applications, ranging from high-tensile-strength fibers to nonlinear optics and optoelectronics. In order to relate the material properties of LCPs to molecular structure, the degree of alignment as well as the mobility of the different structural units must be determined. This calls for highly selective analytical tools like NMR. In fact, pulsed ^2H NMR of selectively deuterated systems^{31,32} as well as multidimensional NMR³³ have provided already a wealth of information about the structure and dynamics of these systems.

As a specific example, let us consider a side group LCP as depicted in Figure 8(a). The development of such materials has been stimulated by the concept that the mesogens with their tendency to form ordered structures can be decoupled from the polymer chain with its tendency to form a random coil by inserting a flexible spacer. By advanced 3D MAS NMR of ^{13}C in natural abundance, involving rotor-synchronized detection of molecular order with sideband separation,³⁴ the alignment of all structural units can be studied simultaneously. Figure 8(b) displays a 3D MAS spectrum of the frozen smectic

Figure 8 Molecular order in calamitic liquid crystalline side group polymers: (a) spacer model; (b) 3D CP MAS NMR spectrum of ^{13}C in natural abundance; (c) order parameters of different functional groups derived from it. For details see Titman et al.³⁴

LCP aligned in the liquid crystalline phase in the magnetic field. Each dot in the spectrum corresponds to a single spinning sideband of a single resolvable carbon in the repeat unit, from which the degree of alignment of the corresponding unit can be retrieved. The results of the analysis in terms of order parameters $\langle P_2 \rangle, \dots, \langle P_8 \rangle$ are displayed in Figure 8(c). This not only reveals a pronounced order gradient from the aligned mesogen to the disordered chain, it also shows that the acrylic carbonyl group exhibits much higher order than the hydrocarbon units of the main chain. Because of its selectivity, high-resolution solid state NMR is able to reveal that the carbon–carbon bond that links the acrylic carbonyl to the main chain plays a crucial role in the decoupling of the ordered side groups from the disordered polymer chain. This information is needed to understand the differences in chain order for different backbones,³¹ and the rheological behavior³⁵ as well as the ordering behavior of mechanically deformed LC elastomers.³⁶

3.3 Molecular Dynamics

The molecular dynamics of polymer chains depend first of all on their phase structure. Most synthetic polymers are amorphous, forming a coiled shape as indicated in Figure 9(a). Stereoregular polymers can crystallize. However, owing to the enormous loss of conformational degrees of freedom, crystallization is incomplete and leads to semicrystalline materials that typically form lamellar structures, as depicted in Figure 9(b). Different aspects of the molecular dynamics are important in amorphous and semicrystalline systems, and the application of multidimensional solid state NMR has recently provided detailed information about chain dynamics for both cases.¹⁴

3.3.1 Rotational Motions in Crystalline Regions

Two-dimensional exchange NMR provides detailed information about the geometry of rotational motions. This was demonstrated, among other ways, by ^2H 2D exchange NMR of poly(vinylidene fluoride) (PVF₂).³⁷ This polymer is of particular interest because of its electrical properties.³⁸ The 2D spectrum for the crystalline α phase at 370 K, shown in

Figure 9 Schematic representation of (a) amorphous and (b) semicrystalline polymers

Figure 10(a), in addition to a well-defined powder spectrum (Pake pattern) along the diagonal, displays well-developed elliptical exchange ridges. The latter indicates jump motions of the PVF₂ chains through the crystal lattice, which interchange C– ^2H bond directions differing by 113° , in agreement with the refined crystal structure. Altogether, 16 conformational defects had previously been proposed to be responsible for the chain dynamics in this polymer. Together with knowledge of the change in dipole moment generated by the motion, a specific conformational change $tg\bar{t}\bar{g} \leftrightarrow \bar{g}t\bar{g}t$ of a chain defect

Figure 10 Chain motion in the crystalline α phase of poly(vinylidene fluoride), (PVF₂).³⁷ (a) Experimental ^2H 2D exchange NMR spectrum at $T = 370\text{ K}$, mixing time $t_m = 200\text{ ms}$. (b) Geometry of the conformational jumps, T and G refer to *trans* and *gauche* conformations of the respective bonds, while A and C describe the direction of the dipole moment with respect to the a and c crystal axes

[Figure 10(b)] was identified as being responsible for the mechanical and dielectric relaxation in the crystalline regions of this polymer.³⁷

In other semicrystalline polymers like polypropylene, poly(oxyethylene), and poly(ethylene oxide), slow chain motions in the crystalline regions have been detected, and 2D exchange NMR of ^2H and ^{13}C has identified these motions as being due to helical jumps.^{12–14,39}

3.3.2 Chain Diffusion between Crystalline and Amorphous Regions

Not only can two-dimensional exchange NMR detect molecular dynamics via the resulting rotations of individual groups of the monomer unit, but it is also able to detect chain diffusion from crystalline to amorphous regions in semicrystalline polymers.⁴⁰ Although occasionally postulated,⁴¹ this process has not been accepted as a general concept, most likely because of lack of experimental evidence.

Our 2D experiment makes use of the fact that, under MAS, the all-*trans* conformation in the crystalline regions of polyethylene (PE) has an isotropic chemical shift that differs by approximately 2 ppm from that of the *gauche*-containing conformers in the amorphous regions. In the sketch of polyethylene (PE) chains in a crystallite near the interface with an amorphous region shown in Figure 11(a), carbons 1

and 2 would contribute to the “amorphous” signal [marked *a* in Figure 11(b)] and the carbons 9 and 10 would contribute to the “crystalline signal” (marked *c*). The exchange intensity between the ^{13}C signals for CH_2 groups in the crystalline and amorphous regions is clearly visible in Figure 11(b). This directly proves chain diffusion taking CH_2 groups from the crystalline into the amorphous regions and vice versa. This translational diffusion in the solid state results from the well-known α process, assigned to 180° jumps of the chain stems in the crystallites,⁴¹ accompanied by a translation by one CH_2 unit. The quantitative analysis of our 2D NMR and relaxation data yields jump rates in complete agreement with previously reported values (activation energy $E_a = 105 \text{ kJ mol}^{-1}$). It shows that the root-mean-square displacement of individual CH_2 groups amounts to more than 100 nm within 100 s near 360 K, corresponding to a translational diffusion constant of $10^{-14} \text{ cm}^2 \text{ s}^{-1}$. In commercial materials, chain diffusion, as detected here, is suppressed by branching, since it leads to deterioration of the long-term mechanical properties owing to creep.

3.3.3 Chain Motions of Amorphous Polymers at the Glass Transition

As an amorphous polymer is heated above its glass transition temperature T_g , its mechanical properties change significantly within a temperature range of typically 20–30 K where the material transforms from a glassy solid to a highly viscous melt.^{1–3,42} (An excellent overview of dynamic phenomena at the glass transition is given in special issues of the *Journal of Non-Crystalline Solids*.⁴³) However, the dynamic processes on a molecular level, responsible for these changes in the macroscopic behavior, are not sufficiently well characterized. Multidimensional exchange NMR has now provided information about the chain dynamics at the glass transition in unprecedented detail.¹⁴

Conformational (*trans*–*gauche*) transitions are usually considered as an important aspect of polymer chain dynamics in the melt and in solution.⁴⁴ Slow conformational transitions at temperatures slightly above T_g have indeed been observed in various polymers.^{24,45} This is demonstrated for aPP in Figure 12. The ^{13}C 2D exchange NMR spectrum was recorded under rapid MAS, such that isotropic lines were obtained. The conformational exchange clearly manifests itself by pronounced cross peaks between the lines corresponding to the $t^*.t$ and the $t^*.g$ conformers discussed earlier (see Figures 5 and 6).

However, as pointed out, for example, by Helfand et al.,⁴⁶ such motions need not be strictly local processes described by kink⁴⁷ or three-bond motions on a diamond lattice,⁴⁸ involving rotations by well-defined angles about spatially fixed C–C axes. Conformational transitions may also arise from relaxation processes involving longer chain units, leading to translational and angular displacements of different amplitudes of the corresponding monomer units. Indeed, ^2H 2D exchange NMR of aPP of the chain dynamics does not show any sign of preferred rotational angles.⁴⁹ As demonstrated in Figure 12(b), the ^2H spectra could be fitted adequately on the basis of an isotropic rotational diffusion model involving small angular steps.

The correlation times of the conformational dynamics agree remarkably well with those of the rotational motions. This is

Figure 11 Chain diffusion in solid polyethylene, (PE).⁴⁰ (a) Sketch of PE chains in a crystallite, near the interface with an amorphous region. (b) ^{13}C 2D MAS NMR spectrum at $T = 363 \text{ K}$; signal of the crystalline regions suppressed through single pulse irradiation. (c) Arrhenius plot of jump rates for the primary step of chain diffusion in PE

Figure 12 Chain motion of atactic polypropylene (aPP), at the glass transition. (a) ^{13}C 2D CP MAS spectrum at $T = 250\text{ K}$ ($T_g + 12\text{ K}$) and mixing time $t_m = 500\text{ ms}$. The cross peaks indicate conformational transitions.⁴⁵ (b) ^2H 2D exchange NMR spectrum at $T = 270\text{ K}$ ($T_g + 17\text{ K}$) and mixing time $t_m = 50\text{ ms}$. The broad exchange features indicate rotational motions, which can be fitted by small-angle step rotational diffusion;⁴⁹ see also the reorientational angle distribution obtained from a quantitative fit of the spectrum. (c) Mean correlation times for the various aspects of the chain dynamics in different polypropylene samples plotted versus reduced temperature from ^{13}C and ^2H NMR; for details see Zemke et al.,²⁴ Schaefer et al.,⁴⁹ and Dekmezian et al.⁵⁰

demonstrated in Figure 12(c), where mean correlation times determined by various techniques on different amorphous PP samples are shown.²⁴ Also included are values determined earlier through ^{13}C spin-lattice relaxation times by Mandelkern and co-workers⁵⁰ at elevated temperatures. All these correlation times can be fitted by the Williams-Landel-Ferry (WLF) equation⁴² describing mechanical relaxation over more than 12 orders of magnitude. Thus, as noted before,^{45,48,51} the timescales of the chain dynamics as probed for individual CH_2 units by 2D NMR are in excellent agreement with those of the collective processes responsible for the strong temperature dependence of the α process at the glass transition.^{3,42,43}

3.3.4 Geometry of Chain Motion in Amorphous Polymers

As noted in the preceding section, conformational transitions in a vitrifying melt need not be strictly local processes involving rotations by well-defined angles in a potential that is static with respect to an external reference frame. If conformational transitions do indeed arise from relaxation

processes of larger chain units⁴⁶ involving translational and angular displacements of different amplitude along such a unit then the rotational potential around a given C–C bond, which with respect to an internal frame would still look like that plotted in Figure 5(b), can be displaced by large angles after a conformational transition has occurred around that bond. Such displacements are difficult to prove experimentally. In fact, we are unaware of techniques or attempts in other groups that tackle this question. Yet it is of profound importance in order to understand the coupling of molecular dynamics and macroscopic properties such as viscosity or dynamic mechanical relaxation. Indeed, there are several ways in which such angular displacements manifest themselves in multidimensional NMR experiments.¹⁴ A particularly direct way of proving their existence is provided by 3D exchange NMR. There the orientation of a selected group is measured at three distinct points in time through their frequencies ω_1 , ω_2 , ω_3 , displaced by two mixing times t_{ma} and t_{mb} [Figure 3(a)]. If the conformational transitions occurred in a potential that was static on average, at least on the timescale of several jumps,

the groups under study should exhibit long-term orientational memory,¹⁴ which should manifest itself by jumps back to the starting orientation. These can directly be probed by 3D exchange NMR, where return jumps lead to ridges with $\omega_1 = \omega_3$.

Poly(vinyl acetate) (PVAc) provides a means to check such long-term orientational memory by 3D exchange NMR. This is due to the fact that, even in the ^{13}C NMR spectrum of a nonrotating sample, the powder pattern of the carbonyl carbon is completely separated from the signals of the aliphatic carbons. Thus it was possible to record a complete 3D exchange spectrum for that position.¹⁴ In Figure 13, it is compared with a 3D exchange NMR spectrum of poly(ethylene oxide), (PEO), a highly disordered semicrystalline polymer.⁵² In both cases, the mixing times t_{ma} and t_{mb} were set equal. The ridge in the diagonal plane $\omega_1 = \omega_3$ due to return jumps indicating long-term orientational memory is a prominent feature of the PEO spectrum [Figure 13(b)], but is absent from the PVAc spectrum [Figure 13(a)]. Thus, the disordered 7_2 helix of PEO has a finite probability to return to the start position even after numerous helical jumps,¹⁴ whereas the repeat unit of PVAc apparently loses its orientational memory at each large-angle jump. This proves that in a semicrystalline polymer the chain moves in a potential that, on average, is static, whereas no such average static potential can be associated with the chain motion of an amorphous polymer above T_g . This also means that a tight coupling of molecular and cooperative dynamics must exist in amorphous polymers.

3.3.5 Nature of Nonexponential Relaxation above T_g

The time dependence of relaxation processes in amorphous polymers above T_g cannot be described by single exponentials. This is inferred from nonexponential correlation functions measured by conventional relaxation techniques,^{42,43} and also shows up in 2D exchange NMR.^{14,49,51} This is illustrated in Figure 14 for poly(vinyl acetate), where again the carbonyl carbon only is considered.⁵³ From the ratio of diagonal and off-diagonal intensity of 2D exchange spectra as a function of t_m , the correlation function $\langle \omega(0) \omega(t_m) \rangle$ is obtained and is plotted in Figure 14(a). The nonexponential decay is consistent with a stretched exponential Kohlrausch–Williams–Watts function

Figure 13 ^{13}C 3D exchange CP NMR spectra without MAS, comparing the chain motion in an amorphous and in a crystalline polymer: (a) poly(vinyl acetate), (PVAc), at $T = 311\text{ K}$ ($T_g + 10\text{ K}$) and mixing times $t_{\text{ma}} = t_{\text{mb}} = 500\text{ ms}$; only the carbonyl region of the spectrum is shown; (b) poly(ethylene oxide), (PEO), at $T = 225\text{ K}$ and $t_{\text{ma}} = t_{\text{mb}} = 1\text{ s}$; frequency scales in (a) and (b) are different for better comparison¹⁴

$\exp [-(t/\tau_0)^\beta]$ ^{54,55} with a mean correlation time $\tau_0 = 20\text{ ms}$ and $\beta = 0.3$, which translates into an asymmetric distribution of correlation times with a width of approximately three decades, as plotted in Figure 14(b).

The nature of such observations has been a matter of dispute for a long time. Two conflicting views offer explanations in terms of (i) a spatially heterogeneous distribution of correlation times (parallel processes, nonergodic) or (ii) an intrinsically nonexponential loss of correlation in a homogeneous system (a serial process, ergodic). Experimental techniques that are able to distinguish these views on a timescale relevant for the glass process, i.e., a second or so, were lacking. This distinction can be achieved by multidimensional exchange NMR, where the orientation of the same molecule can be measured by three or more subsequent points in time. In the reduced 4D exchange experiment [Figure 14(c)], we keep the first two evolution times t_1 and t_2 constant and equal. Units for which $\omega(\theta_1) = \omega(\theta_2)$, i.e., that have the same orientation before and after t_{ma} , generate a stimulated echo. The magnetization generated by the ‘slow molecules’ is then stored by a 90° pulse, and a 2D exchange spectrum of that selected subensemble of slow molecular units is recorded at later times, after t_{mb} , constituting a reduced 4D exchange spectrum.

In Figure 14(d)–(f), two reduced 4D exchange spectra are compared with a reference 2D NMR spectrum. The mixing times t_{ma} and t_{mc} were kept equal and comparable to τ_0 . Whereas the 2D spectrum for that mixing time [Figure 14(d)] is a superposition of a diagonal ridge and broad exchange features, the reduced 4D spectrum for $t_{\text{mb}} = t_{\text{ma}} = t_{\text{mc}}$ exhibits the diagonal ridge only [Figure 14(e)]. This proves directly that the system is heterogeneous (nonergodic) on the timescale of the mean correlation time τ_0 , since the spectrum of the selected subensemble is entirely different from that of the total ensemble. However, on lengthening t_{mb} by two orders of magnitude (point V in Figure 14(b)), considerable off-diagonal intensity is observed [Figure 14(e)]. This means that a significant number of units that were slow initially ($\tau \gg \tau_0$) have changed their correlation time to $\tau < \tau_0$. Thus, in the vitrifying melt, fluctuations are detected that change the reorientational dynamics of chain units. Markedly, these fluctuations causing the system to become homogeneous (ergodic) occur on timescales within the “long-time tail” of the distribution of correlation times. These experiments clearly show that, during the glass transition, the molecular units undergo non-Markovian motion with time-dependent correlation times, though not on the timescale of the mean correlation time but rather in a process limiting the longest correlation time.

3.3.6 Local Motions in the Glassy State and Their Relation to Mechanical Properties

The favorable mechanical properties of glassy polymers stem from relaxation processes that are possible even in the solid state.^{2,3,42} However, little is known about the geometry of molecular dynamics responsible for such processes. Mechanical measurements^{56,57} and ^2H 1D NMR⁵⁸ have previously established a connection between the low-temperature γ relaxation and phenylene ring motions in polycarbonate (PC), a polymer with especially favorable mechanical properties. The ring motion was identified as a flip by 180° [Figure 1(f)]. This was subsequently verified by ^{13}C NMR.^{59,60} However,

Figure 14 Nature of nonexponential loss of correlation above the glass transition.⁵³ (a) Nonexponential decay of correlation function with experimental points for poly(vinyl acetate), (PVAc). (b) Distribution of correlation times $G(\tau)$ derived from it. (c) Pulse sequence for reduced 4D exchange NMR. (d) Experimental and simulated ^{13}C 2D exchange NMR spectrum at $T = 320\text{ K}$ ($T_g + 20\text{ K}$) and mixing time $t_m = 10\text{ ms}$. (e) Experimental and simulated ^{13}C reduced 4D exchange NMR spectrum at the same temperature and mixing times $t_{ma} = t_{mb} = t_{mc} = 10\text{ ms}$. (f) Similar to (e), but with $t_{mb} = 1\text{ s}$ and $t_{ma} = t_{mc} = 10\text{ ms}$

the NMR lineshapes are unable to provide information about the detailed geometry of the phenylene motion at low temperatures, where it occurs on a timescale of hundreds of milliseconds, which can be probed directly by mechanical relaxation experiments. Again, such slow molecular dynamics can be detected by 2D exchange NMR, as demonstrated in Figure 15. The ^2H 2D exchange NMR spectrum of a sample selectively deuterated at the phenylene rings, PC- d_4 , exhibits somewhat broadened elliptical ridges [Figure 15(a)],⁶¹ which confirm the geometry of the phenylene motion as rotations around the *para* axis as indicated. However, the flip typically does not involve a rotation by exactly 180° , but by angles that can differ substantially from this mean value [Figure 15(b)]. This means that, after a rotation, the phenylene group finds itself in a slightly different environment, which readily explains the connection between this molecular dynamic process and the mechanical relaxation. Indeed, when the 2D spectrum is recorded under tensile stress, such that the sample is stretched up to the nonlinear region, yet below the yield point, the angular uncertainty in the flip angle increases further⁶¹ [Figure 15(b)]. This is consistent with the reported increase in the strength of the mechanical relaxation under such conditions.⁶² The timescale of the phenylene flips is not uniform but displays a broad distribution of correlation times⁶³ reflecting different activation energies in different regions of the sample.

3.3.7 Geometry of Side Group Motion in the Glassy State

The β relaxation observed in poly(methyl methacrylate), (PMMA), by means of both dielectric and dynamic-mechanical relaxation,³ is often considered as the archetype of a localized (β) relaxation in polymers. Since this relaxation is very prominent in dielectric relaxation, it has traditionally been attributed to the carboxyl side group with its large dipole moment [Figure 16(a)]. However, quantitative analysis of relaxation strengths in both techniques is virtually impossible. Thus, neither was the geometry of the side group motion known, nor whether all or only a fraction of the groups are participating in the motion in the glassy state. A study involving both ^{13}C and ^2H multidimensional exchange NMR gave answers to these questions.⁶⁴ In fact, the geometry of the side group motion turned out to be more complex than originally anticipated. It involves ill-defined flips by $180^\circ \pm 20^\circ$ about the C–C bond linking the carboxyl side group to the polymer backbone. This flip motion is coupled to a “rocking” motion about the local chain axis [Figure 16(a)], with a 20° root-mean-square amplitude. This motion can be detected in both ^{13}C and ^2H NMR, whereas the flip shows up only in the ^{13}C spectra. In the latter, the two coupled motional processes manifest themselves in the unstructured exchange intensity covering most of the 2D plane [Figure 16(b)], whereas the angular more restricted “rocking” motion leads to the exchange intensity in the ^2H spectrum being restricted to the vicinity of the diagonal⁶⁴ [Figure 16(c)].

Figure 15 Phenylene motion and mechanical behavior in bisphenol-A-polycarbonate, (PC)⁶¹. (a) ^2H 2D exchange NMR spectrum of phenylene deuterated sample at $T = 223$ K, mixing time $t_m = 500$ ms. The elliptical figures (see inset) correspond to $\Phi = 180^\circ \pm 25^\circ$ phenylene flips with reorientational angle distributions shown in (b). (c) After application of 50 MPa stress, a significant broader distribution of flip angles around the same mean 180° is observed

These findings are ascribed to the fact that the asymmetric side group, after the flip, does not fit into its original environment as depicted in Figure 16(d). Remarkably, the side group exhibits long-term orientational memory. As checked by ^{13}C 3D exchange NMR, despite the featureless exchange intensity in the 2D spectrum, the reorientation of each segment involves only two, relatively well-defined, potential energy minima. Thus, after two subsequent flips, the carboxyl group is back to almost the initial orientation [Figure 16(d)]. It is also important to realize that in the glassy state of PMMA, only about 50% of the side groups can undergo this motion. Since the side group flip requires the “rocking” motion around a locally extended chain axis, this was related to the fraction of syndiotactic triads in this polymer, which indeed favor extended conformations.⁶⁴

This example demonstrates how complex a seemingly simple side group motion in a glassy polymer can be. The complex geometry of the side group dynamics stems from its asymmetry, since the packing apparently does provide enough free volume for a methyl group, in which it could fit after a flip. Obviously, this finding should be of interest not only for

Figure 16 Side group motion in poly(methyl methacrylate), (PMMA).⁶⁴ (a) Sketch of the PMMA geometry and the principal axes for ^{13}C (carboxyl group) and ^2H (O-methyl group) NMR. (b) ^{13}C 2D exchange NMR spectrum at $T = 333$ K and mixing time $t_m = 50$ ms. (c) ^2H 2D exchange NMR spectrum at $T = 355$ K and mixing time $t_m = 500$ ms. (d) Sketch of the dynamics of an asymmetric side group in its correspondingly asymmetric environment, indicating that in order to fit the asymmetric side group into the volume that it had occupied before the flip, a twist around the local chain axis (“rocking” motion) is required

the understanding of the relation between molecular dynamics and the mechanical properties of amorphous polymers, but also in biophysics, where motions of asymmetric side groups are common dynamic processes, e.g., in proteins.⁶⁵

3.4 Heterogeneous Polymers

In heterogeneous polymers, i.e., polymer blends or block copolymers,^{1,2} domain sizes, or structures on the scale from a few to some tens of nanometers, can be investigated by NMR spin diffusion experiments. Thus, NMR is particularly suited for characterizing small domains, nanoheterogeneities, or concentration fluctuations on lengthscales of a few nanometers, where other methods often fail owing to limitations in resolution or contrast. Thus, spin diffusion measurements are well established in solid state NMR of polymers.⁸ Moreover, several advanced approaches exploiting ^1H spin diffusion with highly selective ^{13}C detection have been introduced.¹⁴

3.4.1 Wideline Separation Experiments on Polymer Blends

Spin diffusion experiments require that the different components contained in the sample be distinguished in their

NMR parameters. This is particularly straightforward if the components differ in their mobility. In fact, a long-standing method for a qualitative characterization of molecular mobility is ^1H wideline NMR spectroscopy.⁸ There, rapid large-amplitude motions are detected through the reduction of dipolar linewidths. However, 1D proton lineshapes leave many questions open, since they typically represent superpositions of broad and narrow lines, and their relation to different structural units is often not obvious. In a straightforward combination of ^1H wideline NMR, cross polarization and ^{13}C MAS spectroscopy in a 2D experiment,⁶⁶ it is possible to separate the dipolar patterns for the different structural units (wideline separation, WISE).

The power of this technique is demonstrated in Figure 17, where data on a 50:50 wt% blend of polystyrene, (PS), and poly(vinyl methyl ether), (PVME), cast from toluene, are presented. This blend appears homogeneous by most classical techniques. The ^1H wideline spectrum [Figure 17(a)] consists of a rather featureless superposition of components with different dipolar linewidths, which are nicely separated in the second frequency dimension [Figure 17(b)] and related to their ^{13}C chemical shifts. Substantial motional heterogeneities, PVME being more mobile than PS, are detected despite the fact that the spectrum is recorded about 60 K above the calorific glass transition of the blend. By introducing a mixing time⁶⁶ to allow for spin diffusion, the ^1H lineshapes equilibrate after only 5 ms [Figure 17(c)]. From this, the domain sizes for the regions of different mobility were estimated to be 3.5 ± 1.5 nm. Thus, these advanced NMR techniques reveal substantial motional differences in different regions of this blend, which rather than homogeneous should better be described as nanoheterogeneous.

3.4.2 Domain Sizes from Spin Diffusion Experiments

Another advanced approach towards quantitative use of spin diffusion experiments exploits ^1H spin diffusion after high-resolution ^1H solid state NMR by combined rotation and multiple-pulse spectroscopy (CRAMPS), with high-resolution ^{13}C MAS detection.^{14,16} In a particularly clear-cut case, this technique has been applied to a series of symmetric diblock copolymers of PS and PMMA.¹⁶ In Figure 18(a), the increase

Figure 17 2D WISE NMR separating ^1H wideline spectra for different structural units according to their ^{13}C chemical shifts. (a) Conventional ^1H wideline spectrum of a blend of polystyrene, (PS), and poly(vinyl methyl ether), (PVME). (b) 2D ^1H ^{13}C WISE NMR spectrum at $T = 320$ K, note the different ^1H linewidths for PS and PVME. (c) Similar to (b), but with spin diffusion over a time $t_m = 5$ ms; note that now all lines have equal ^1H linewidths

Figure 18 Spin diffusion as a tool for determining domain sizes in heterogeneous polymers.¹⁶ (a) ^{13}C MAS spectra of the symmetric diblock copolymer PS-*b*-PMMA as a function of the diffusion time t_m after selection of proton magnetization of the methoxy group in PMMA. (b) Signal intensity of the phenyl carbons in PS as a function of t_m for different molecular weights. The numbers indicate the domain sizes obtained from the respective fits

in the carbon signal of the phenyl ring in the PS block after selection of the PMMA block is plotted against the spin diffusion time t_m for various block lengths. The equal lengths of both blocks in the symmetric copolymer ensures a lamellar structure, which makes quantitative analysis of the data easy. PMMA and PS are known to be immiscible. The spin diffusion data yield domain sizes that are consistent with the scaling law $M_n^{0.66}$, where M_n denotes the molar mass of the block, as predicted theoretically.² For comparison, a statistical copolymer, in which no phase separation is possible, and a blend of both homopolymers were included in the data set. The close agreement between experimental intensities and the time dependence calculated from the diffusion equation is apparent in Figure 18(b), and demonstrates that domain sizes between 0.5 and 100 nm can be determined quantitatively.

3.4.3 Packing and Mobility in Rigid Rod Systems

Advanced solid state NMR has also been applied to study the structure and dynamics of advanced polymer materials.³³ As a specific example, consider rigid rod systems consisting of *para*-substituted aromatics as stiff macromolecules, such as polyesters, polyamides and polyimides. These have attracted

Figure 19 2D WISE NMR spectra of aliphatic side chains of various rigid rod macromolecules and structural models derived from them and spin diffusion measurements:⁶⁹ (a) polyester, A-form, PPTE-A; (b) polyimide PPPI; (c) polyamide, PPTA

considerable interest because of their unusual mechanical properties.⁶⁷ When processed from a nematic mesophase, the parallel packing of the stiff macromolecules results in high-modulus fibers. In order to increase the processability of such materials, flexible side chains are attached. However, owing to the inherent incompatibility of stiff backbone and flexible side chains, layer structures are formed where these different building elements are separated⁶⁸ (see Figure 19). Depending on the packing requirements of the stiff macromolecules, highly crystalline [form B, Figure 19(b)] or disordered amorphous [form A, Figure 19(a) and (c)] structures are formed. This imposes packing restrictions on the side chains, favoring crystallization or preventing it. Whereas X-ray scattering has been invaluable in establishing the basic features of the packing, it is difficult to provide clear-cut information about the details of the molecular organization in such complex systems.

Here, advanced 2D solid state NMR methods offer interesting alternatives. Figure 19 displays the results of 2D WISE NMR and spin diffusion experiments⁶⁹ on the side chains of a polyester (PPTE-A), a polyimide (PPPI), and a polyamide (PPTA). A high-resolution ^{13}C CP MAS spectrum of the polyimide is also displayed as an insert. The ^1H wideline spectra reflect the molecular dynamics of the different methylene groups. They are superpositions of broad and narrow components, even at the chain end (C_{16}). The different side-chain packings of the three systems—almost homogeneous

with rather extended chain in the polyester PPTE-A, separated crystalline regions with all-*trans* chains and amorphous regions with disordered chains in the polyimide PPPI, and separated regions with extended and disordered chains in the polyamide PPTA—are nicely reflected in the different WISE NMR spectra.⁶⁹

The delicate balance between the organization of the incompatible rigid main chains and flexible side chains in their respective layers thus leads to a considerable variety in the packing. Advanced NMR techniques yield specific information supplementing computer-aided X-ray studies, because NMR is sensitive to conformation, mobility, and spatial proximity of different structural elements.

4 CONCLUSIONS

High-resolution NMR in liquids is an indispensable analytical tool for structural characterization in chemistry, including the stereochemistry of polymers. Particularly in biochemical applications, the necessary spectral resolution can only be achieved, however, by two- and higher-dimensional spectroscopy. An analogous situation is encountered in solid polymers. Unless isotopic labeling is employed, the different anisotropic spin interactions can be separated only via multidimensional techniques. Besides providing highly selective structural information, advanced solid state NMR

offers unique possibilities for characterizing slow molecular dynamics and relating it to macroscopic material behavior.

1 INTRODUCTION

The study of polymer structure, morphology, orientation, order, and chain dynamics by NMR is an extremely active area. In this article, the application of NMR techniques to selected aspects of polymer physics will be addressed, and these have been chosen in order to show how NMR can provide complementary and additional information to that obtained by other spectroscopic techniques and by mechanical measurements. The first part of the article provides a detailed description of how orientation in particular as well as crystallinity in solid polymers can be quantified using proton second-moment and lineshape analysis. This then leads into an explanation of how relaxation time measurements can give an insight into the nature of polymer relaxations and transitions, and finally we discuss the application of NMR to the study of polymer networks in the melt. A more detailed introduction to each of these areas will be found at the beginning of the relevant section.

2 MOLECULAR ORIENTATION

In many commercial applications of polymers, molecular orientation is introduced as a means of enhancing properties. This is the case for fibers and films, where the production of a highly ordered aligned structure can be used to give increased stiffness and strength, as well as improvements in chemical resistance and thermal stability. Orientation is also a valuable tool for the polymer physicist, because it can often enable more precise relationships to be established between structure and properties and to gain a more precise understanding of molecular relaxation processes. This is essentially a result of the greater complexity of structure and properties observed in an oriented polymer and the correspondingly greater discrimination that can be achieved, the increase in precise information gained usually leading to greater understanding.

NMR studies of oriented polymers are most valuable when they are combined with other structural techniques such as X-ray diffraction, infrared and Raman spectroscopy and with measurements of physical properties, especially mechanical and dielectric relaxation. The starting point for a quantitative

understanding at a molecular level for all these techniques is to consider that the bulk polymer is an aggregate of anisotropic structural units.

At the simplest level, consider a pair of identical nuclei of spin- $\frac{1}{2}$ (i.e. protons). The dipole-dipole interaction will give rise to a doublet signal with linewidth splitting

$$\Delta B = \frac{\mu_0}{4\pi} \frac{3\gamma\hbar}{r^3} (3 \cos^2 \beta - 1) \quad (1)$$

where β is the angle between the line joining the protons and the field B_0 . In some oriented polymers where the predominant dipolar interactions arise from a proton pair, e.g. CH_2 in polyethylene $(\text{CH}_2)_n$ and poly(vinylidene fluoride) $(\text{CH}_2\text{CF}_2)_n$ or the proton pairs on each side of a phenyl ring in liquid crystalline copolyesters, such simple doublet structures can be observed with some broadening due to other internuclear dipolar interactions, and the doublet splitting will be dependent on the direction of B_0 according to the function $3 \cos^2 \beta - 1$.

For a more quantitative discussion, it is usual to use the Van Vleck¹ equations, which relate the even moments of the lineshape to all the intermolecular distances in the polymer. For an absorption line described by $f(B)$, the n th moment is defined by

$$\begin{aligned} \langle \Delta B^n \rangle &= \langle (B - B^*)^n \rangle \\ &= \frac{\int_{-\infty}^{\infty} f(B) (B - B^*)^n d(B - B^*)}{\int_{-\infty}^{\infty} f(B) d(B - B^*)} \end{aligned} \quad (2)$$

where B^* is the applied field at the center of resonance.

The Van Vleck second-moment equation is

$$\langle \Delta B^2 \rangle = \left(\frac{\mu_0}{4\pi} \right)^2 \frac{G}{N} \sum_{j,k} r_{jk}^{-6} (3 \cos^2 \beta_{jk} - 1)^2 \quad (3)$$

where $G = \frac{3}{2} I(I+1) \gamma^2$, I is the nuclear spin number ($= \frac{1}{2}$ for protons), N the number of nuclei over which the sum is taken, r_{jk} the length of the vector joining nuclei j and k , and β_{jk} the angle between the vector r_{jk} and the direction of the steady magnetic field B_0 . Equation (3) ignores any interactions with nonresonant nuclei, and can be seen to be a direct generalization of equation (1).

It is not difficult to envisage how equations (1) and (3) can describe the changes in the NMR signal for an isolated proton pair or for a single crystal of a solid as the direction of B_0 is varied. In practice, polymers are usually not fully aligned, but there is a distribution of molecular orientations, depending critically on the fabrication processing. To develop a quantitative treatment, it is assumed that the polymer can be regarded as an aggregate of anisotropic units of structure, each of which possesses the properties of the fully oriented polymer. In one of the first applications of this approach, for polyethylene, it was assumed that the structural units were an infinite crystal lattice. Because the NMR second moment depends primarily on nearest-neighbor interactions [the r_{ij}^{-6} term in equation (3)], it is only necessary to calculate interactions accurately within a range of about 0.5 nm. This means that quantitative studies of NMR anisotropy can be extended successfully to liquid crystalline polymers and even amorphous polymers.

2.1 Definition of Orientation and Orientation Distribution Functions

The bulk polymer is usually in the form of a film or fiber, with overall orthorhombic or hexagonal symmetry, respectively. A system of rectangular coordinate axes $OX_1X_2X_3$ can be chosen fixed in the polymer sample, conventionally with the initial draw direction in the film or the fiber axis as X_3 , and X_2 as the normal to the film plane (Figure 1). A second set of axes $Ox_1x_2x_3$ is chosen in the structural unit, which is also implicitly assumed to have at least orthorhombic symmetry. (This is not always true at a molecular level, which leads to a further degree of complication.) The orientation of the structural unit with respect to the bulk polymer is defined by the three Euler angles as shown in Figure 1, which represent the three successive rotations through angles ψ , ϕ and θ that would bring the $Ox_1x_2x_3$ axes into exact coincidence with the $OX_1X_2X_3$ axes.

For an aggregate of units, the distribution of orientations is then described by a function $N(\theta, \phi, \psi)$, where $N(\theta, \phi, \psi) \sin \theta d\theta d\phi d\psi$ is the fraction of units whose axes lie in the solid angle $\sin \theta d\theta d\phi d\psi$. It is usual to express this function in a series of generalized spherical harmonic functions

$$N(\theta, \phi, \psi) = \sum_{l=0}^{\infty} \sum_{m=-l}^{+l} \sum_{n=-l}^{+l} P_{lmn} Z_{lmn}(\cos \theta) e^{-im\phi} e^{-in\psi} \quad (4)$$

where the Z_{lmn} are generalizations of the Legendre function, and a non-normalized form of Z_{lmn} is chosen that makes $P_{000} = 1$ and P_{100} equal to the average over the distribution of the l th-order Legendre polynomial in $\cos \theta$.

Although we now have the basis for a general theory, it is instructive (and often adequate in practice) to consider an aggregate of units with fiber symmetry (i.e. defined by the orientation of the Ox_3 axis) where the aggregate also has fiber symmetry (so that the molecule orientation is defined only by the orientation of the Ox_3 axes with respect of the OX_3 axis of

the bulk sample). The distribution function equation (4) then reduces to

$$N(\theta) = \sum_{l=0}^{\infty} (l + \frac{1}{2}) \langle P_l(\cos \theta) \rangle P_l(\cos \theta) \quad (5)$$

where $\langle P_l(\cos \theta) \rangle = \int_0^\pi N(\theta) P_l(\cos \theta) \sin \theta d\theta$ and the orientation distribution is described by two principal averages

$$P_{200} = \langle P_2(\cos \theta) \rangle = \frac{1}{2} \langle 3 \cos^2 \theta - 1 \rangle \quad (6)$$

$$P_{400} = \langle P_4(\cos \theta) \rangle = \frac{1}{8} \langle 3 - 30 \cos^2 \theta + 35 \cos^4 \theta \rangle \quad (7)$$

P_{200} is the well-known Hermans orientation function,² which is proportional to the birefringence in an optically anisotropic polymer.

It is now necessary to develop the relationship between the anisotropy of the NMR signal as determined say from the second moment, equation (3), and therefore related to a function of the angle β , which defines the angle between the internuclear vectors and the steady magnetic field, and the orientation distribution function for the units of structure, which is defined by the spherical harmonic average functions.³ The second-moment anisotropy, equation (3), is written as

$$\langle \Delta B^2 \rangle = \left(\frac{\mu_0}{4\pi} \right)^2 \frac{4G}{N} \sum_{j,k} r_{jk}^{-6} P_2^2(\cos \beta_{jk}) \quad (8)$$

First, the orientation of given internuclear vector is defined by polar and azimuthal angles (Ξ, η) as shown in Figure 2(a). Because the structural units are transversely isotropic, the second moment will involve functions of Ξ only, the functions of η being replaced by their average values.

Similarly, although the orientation of each structural unit must be defined by polar and azimuthal angles θ and ϕ as shown in Figure 2(b), because the bulk sample is also transversely isotropic, the observed second moment will depend only on P_{200} and P_{400} , the functions involving ϕ taking fixed average values.

Finally, the magnitude of $\langle \Delta B^2 \rangle$ depends on the direction of B_0 with respect to the sample axes, which is defined by polar and azimuthal angles Δ and Δ_ϕ , as shown in Figure 2(b). Again, because we assumed uniaxial symmetry for both the sample and the structural units, $\langle \Delta B^2 \rangle$ will depend only on Δ , because there is no preferred orientation in the plane normal to OX_3 .

Figure 2 Polar and azimuthal angles used for relating second-moment anisotropy to the orientation distribution function

The assumptions of uniaxiality for sample and structural units enables us to use the Legendre addition theorem to write

$$\langle P_2^2(\cos \beta_{jk}) \rangle_{\eta_{jk}, \phi} = \sum_l a_l P_l(\cos \theta) P_l(\cos \xi_{jk}) P_l(\cos \Delta) \quad (9)$$

(where the subscripts on the angular brackets $\langle \rangle$ indicate the angles over which the average is taken) and the second moment $\langle \Delta B^2 \rangle$ as

$$\langle \Delta B^2 \rangle = \left(\frac{\mu_0}{4\pi} \right)^2 4G \sum_{l=0,2,4} a_l S_l P_l(\cos \Delta) \langle P_l(\cos \theta) \rangle \quad (10)$$

where

$$S_l = \frac{1}{N} \sum_{j>k}^N P_l \cos(\xi_{jk}) r_{jk}^{-6} \quad (11)$$

and $a_0 = \frac{1}{5}$, $a_2 = \frac{2}{7}$, $a_4 = \frac{18}{35}$. The second-moment anisotropy can therefore be seen to depend on the direction of $\mathbf{B}_0$ through the term $P_l(\cos \Delta)$, the orientation distribution averages P_{200} and P_{400} , and the quantities S_l , which we call the lattice sums and which can be calculated from knowledge of the spatial coordinates of the magnetic nuclei.

2.2 NMR Anisotropy When There are Molecular Motions

In this section, we shall consider the situation where the NMR signal is narrowed owing to molecular motion but the molecular orientation is essentially retained. We shall confine the discussion to molecular rotation about a single axis, and not discuss the situation that occurs in the melt or even in the solid at temperatures close to the melting point, where rotations about several axes occur together with diffusion of the molecules.

Where molecular motion occurs, the dipolar interaction terms must be time-averaged, so that, for example, the second moment is now

$$\langle \Delta B^2 \rangle_{\text{motion}} = \left(\frac{\mu_0}{4\pi} \right)^2 \frac{G}{N} \left\langle \frac{3 \cos^2 \beta_{jk} - 1}{r_{jk}^3} \right\rangle_{\text{motion}} \quad (12)$$

The evaluation of equation (12) for all dipolar interaction terms in a polymer in general involves somewhat laborious calculations. As an illustration, we can consider the case of the proton pair interaction only in a polyethylene fiber with full orientation and rotation of the chain around its axis at a frequency greater than the linewidth in hertz. The length of the intermolecular vector $\mathbf{r}$ is unchanged by the motion, and the contribution to the second moment from the proton pair interaction is

$$\begin{aligned} \langle \Delta B^2 \rangle_{\text{motion}} &= \left(\frac{\mu_0}{4\pi} \right)^2 \frac{G}{N} \frac{3 \cos^2 \beta - 1}{r^6} \\ &= \left(\frac{\mu_0}{4\pi} \right)^2 \frac{5}{16} \langle \Delta B^2 \rangle_{\text{iso}} (3 \cos^2 \Delta - 1)^2 \end{aligned} \quad (13)$$

where $\langle \Delta B^2 \rangle_{\text{iso}}$ is the rigid lattice isotropic second moment and Δ is the angle between the fiber axis and $\mathbf{B}_0$. In terms of

the more sophisticated development using spherical harmonic analysis,⁴ the equation equivalent to equation (10) is

$$\langle \Delta B^2 \rangle = \left(\frac{\mu_0}{4\pi} \right)^2 \frac{4G}{N} S \sum_l a_l P_l(\cos \Delta) \langle P_l(\cos \theta) \rangle \quad (14)$$

where S is a lattice sum defined by

$$S = \sum_{j>k} r_{jk}^{-6} P_2^2(\cos \xi_{jk}) \quad (15)$$

and may also be written as

$$S = \sum_{j>k} r_{jk}^{-6} \sum_l a_l P_l(\cos \xi_{jk}) \quad (16)$$

2.3 Theoretical Predictions of Orientation Distribution Functions from Models for Molecular Alignment

Theoretical predictions of molecular orientation stem principally from two different but related mathematical models. These models seek to relate the molecular alignment to the macroscopic deformation, i.e., the degree of permanent strain, usually defined in terms of the principal extension ratios $\lambda_1, \lambda_2, \lambda_3$ related to a set of rectangular coordinate axes 1, 2, 3, where λ_1 is the ratio of the length of a line in the 1 direction in the deformed polymer to its length in the undeformed polymer, and similarly for λ_2 and λ_3 .

The first model, originally proposed by Kratky⁵ for crystalline orientation in a semicrystalline polymer, assumes that the polymer consists of an aggregate of transversely isotropic units whose symmetry axes rotate on deformation in the same manner as joining pairs of points in the bulk material, which is assumed to deform at constant volume. For uniaxial deformation $\lambda_1 = \lambda$ and $\lambda_2 = \lambda_3 = \lambda^{-1/2}$, and it can be shown that

$$P_{200} = \frac{1}{2} \left[\frac{2\lambda^3 + 1}{\lambda^3 - 1} - \frac{3\lambda^{1/2} \cos^{-1} \lambda^{-3/2}}{(\lambda^3 - 1)^{3/2}} \right] \quad (17)$$

$$\begin{aligned} P_{400} &= \frac{1}{8} \frac{35\lambda^6}{(\lambda^3 - 1)^2} \left[1 + \frac{1}{2\lambda^3} - \frac{3 \cos^{-1} \lambda^{-3/2}}{2(\lambda^3 - 1)} \right] \\ &\quad - \left[\frac{30\lambda^3}{\lambda^3 - 1} \left(1 - \frac{\cos^{-1} \lambda^{-3/2}}{\lambda^3 - 1} \right) + 3 \right] \end{aligned} \quad (18)$$

Similarly, it is possible to calculate P_{200} , P_{220} , etc. for a biaxially oriented aggregate.

This deformation scheme ignores the fact that, on deformation, the line joining two points in the bulk polymer will in general change its length as well as rotate. It has therefore been called the 'pseudoaffine' deformation scheme to distinguish it from the 'affine' deformation scheme, which was devised by Kuhn and Gr $\ddot{u}$ n⁶ for the deformation of a rubber-like network where the vectors joining the junction points of the network both rotate and change their length, and the chain segments between the junction points adopt the most probable distribution of molecular orientations consistent with maximizing the entropy for the new length between these junction points

in the deformed state. For this deformation scheme, the true network of chains can be modeled by an idealized network of chains consisting of rotatable rigid segments called random links, each chain containing an identical number N' of such links. Using the Treloar expression for the inverse Langevin function,⁷ it can be shown that

$$P_{200} = \frac{1}{5N'} \left(\lambda^2 - \frac{1}{\lambda} \right) + \frac{1}{25N'^2} \left(\lambda^4 + \frac{\lambda}{3} - \frac{4}{3\lambda^2} \right) + \frac{1}{35N'^3} \left(\lambda^6 + \frac{3\lambda^2}{5} - \frac{8}{5\lambda^2} \right) \quad (19)$$

for uniaxial deformation to an extension ratio λ . Further expressions have been given for P_{200} , P_{220} , etc. in the case of a biaxially oriented rubber network, and

$$P_{400} = \frac{3}{175N'^2} \left(\lambda^4 - 2\lambda + \frac{1}{\lambda^2} \right) + \frac{216}{13475N'^3} \left(\lambda^6 - \frac{4\lambda^3}{5} - \frac{7}{5} + \frac{6}{5\lambda^3} \right) \quad (20)$$

Equations (17)–(20) are shown schematically in Figure 3.

2.4 Experimental Studies of NMR Anisotropy

Quantitative studies of molecular orientation using NMR anisotropy have been largely concerned with second-moment measurements using the theoretical developments leading to equations (10) and (14), which provide information regarding P_{2mn} and P_{4mn} , most usually P_{200} and P_{400} for samples possessing uniaxial symmetry. Fourth-moment measurements

Figure 3 P_{200} and P_{400} as functions of draw ratio λ for (a) the pseudoaffine deformation scheme (uniaxially oriented sample) and (b) the rubber network affine deformation scheme ($N' = 6$, uniaxially oriented sample). have also been used to obtain values for higher-order orientation functions such as P_{600} and P_{800} .

One of the earliest applications of the theory outlined above was to cold-drawn low-density polyethylene,³ where the development of NMR anisotropy was determined from quantitative measurements of the second and fourth moments as functions of the direction of B_0 . A further complication in the analysis arises from the fact that we are dealing with a semicrystalline polymer, i.e., there are crystalline and amorphous regions with different degrees of molecular orientation. It was found adequate to assume that the NMR anisotropy arose entirely from the crystalline regions and that the amorphous regions made a constant contribution in proportion to their concentration. With this assumption, the NMR anisotropy was shown to be consistent with the pseudoaffine deformation scheme [equations (17) and (18) for P_{200} and P_{400} , respectively] (Figure 4). A result of particular practical value was that the values of P_{200} and P_{400} could be used to give a very successful prediction of the mechanical anisotropy, for example, the change in Young's modulus as a function of draw ratio.

A second polymer that has been studied in some detail is poly(ethylene terephthalate), (PET).⁸ There are several major differences with the previous case of PE. First, PET appears to conform on deformation to the rubber network model so that P_{200} and P_{400} are now given by equations (19) and (20). Secondly, an important distinction at a structural level is between *trans* and *gauche* conformations of the glycol residue, and although the crystalline regions are solely *trans*, the amorphous regions can be both *gauche* and *trans* (the so-called 'amorphous *trans*' material).

It has been shown that the NMR anisotropy relates primarily to the all-*trans* material, irrespective of whether this is in the crystalline or amorphous regions. For a quantitative analysis of the NMR anisotropy, the *gauche/trans* ratio must also be determined (e.g., by infrared spectroscopy). The situation is analogous to that for low-density polyethylene, where the fractional crystallinity was required.

Similar studies to the above have been undertaken for many crystalline polymers, including the situation where

Figure 4 The second moment plotted against draw ratio: (a) the observed variation; (b) theoretical variation on pseudoaffine deformation scheme. Reprinted by permission from V. J. McBrierty and I. M. Ward, *Br. J. Appl. Phys. (J. Phys. D)*, 1968, **1**, 1529. © (1968) IOP Publishing Ltd.

molecular motions occur. Particularly notable early investigations were those of Slichter⁹ on polytetrafluoroethylene, Olf and Peterlin¹⁰ on poly(oxyethylene) and polyethylene, and Folkes and Ward⁴ on polyethylene.

Second-moment anisotropy studies have also been analyzed quantitatively for noncrystalline polymers [e.g., poly(methyl methacrylate)] poorly crystalline polymers [e.g., poly(vinyl chloride)], and liquid crystalline polymers (e.g., linear thermotropic copolyesters of hydroxybenzoic acid and hydroxynaphthoic acid). In these polymers, the lattice sums can be estimated by assuming that the magnetic anisotropy arises entirely from the intramolecular interactions, and that the intermolecular interactions are isotropic. The lattice sums for the intramolecular interactions are then calculated exactly for the molecular chains on the basis of a configurational model for the chain, and the intermolecular interactions give a small additional term in the isotropic S_0 lattice sum that can be found from a least-squares fit to the data. In the case of liquid crystalline copolyesters, the existence of random chain substitution is taken into account by Monte Carlo statistics.

2.5 Chemical Shift Anisotropy

In oriented polymers, there is also an effect that can be observed relating to the fact that the chemical shift depends on the direction between the steady magnetic field B_0 and the orientation of the local environment of the resonant nucleus. This is called chemical shift anisotropy. Consider the situation where the chemical shift can be represented by an axially symmetric chemical shift tensor. The position of the resonance line is then given by

$$\sigma(\beta) = \sigma_{\parallel} \cos^2 \beta + \sigma_{\perp} \sin^2 \beta \quad (21)$$

where $\sigma_{\parallel}$ and $\sigma_{\perp}$ are the chemical shifts when the unique axis of the tensor is parallel or perpendicular to B_0 , respectively, and β is the angle between the unique axis and B_0 . In practice, this simple situation is complicated for two major reasons. First, there is a distribution of molecular orientations, so that the total NMR signal will have a lineshape that relates to the distribution with the chemical shift anisotropy for each proton given by equation (21) with the appropriate value of β . Second, this lineshape must also be convoluted with a broadening function to account for relaxation broadening or dipolar interactions. It has been shown to be adequate to approximate these broadening effects by a simple Gaussian function¹¹ (analogous to that procedure for the Pake doublet broadening).

A quantitative treatment of chemical shift anisotropy relates the orientation distribution parameters P_{lmn} to the first-moment anisotropy, i.e., the shift in the center of gravity of the absorption as a function of the direction of B_0 , which is most generally defined by the polar and azimuthal angles Δ and ϕ_{Δ} that this makes with the 3 axis of the sample. Most studies of chemical shift anisotropy have been confined to samples with uniaxial (fiber) symmetry. For this situation, it can be shown that the first-moment anisotropy $\Delta\sigma_1$ is given by

$$\Delta\sigma_1 = \Delta\sigma P_2(\cos \theta) \left(\frac{2}{3} - \sin^2 \Delta \right) \quad (22)$$

where $\Delta\sigma = \sigma_{\parallel} - \sigma_{\perp}$, $\langle P_2(\cos \theta) \rangle$ is the molecular orientation function average, and Δ is the angle between

B_0 and the symmetry axis of the sample (the fiber axis or draw direction). A further complication required to obtain quantitative information is the need to take into account the different chemical shift anisotropies for the crystalline and amorphous regions in a semicrystalline polymer. The first-moment anisotropy is divided into two components, so that

$$\Delta\sigma_1 = f_c \Delta\sigma_{1c} + (1 - f_c) \Delta\sigma_{1a} \quad (23)$$

where f_c is the crystalline fraction, and $\Delta\sigma_{1c}$ and $\Delta\sigma_{1a}$ refer to crystalline and amorphous regions respectively.

Experimental studies of chemical shift anisotropy have now been reported for several polymers. Particularly notable are the pioneering research of Garroway¹² and co-workers and Brandolini et al.¹¹ on poly(tetrafluoroethylene), van der Hart and co-workers¹³ on polyethylene, and more recently Monnerie et al.¹⁴ on liquid crystalline copolyesters.

3 ANALYSIS OF COMPOSITE NMR SPECTRA: DETERMINATION OF RIGID/MOBILE FRACTION AND CRYSTALLINITY

3.1 Broadline Line Shape and Measurements of the Free Induction Decay

Wilson and Pake¹⁵ showed that the broadline (continuous wave) spectra for proton resonance in polyethylene and for fluorine resonance in poly(tetrafluoroethylene) were composite in form, consisting of a broad and a narrow component. These two components were attributed to the crystalline region (broad 'rigid' component) and the amorphous regions (narrow 'mobile' component), respectively. These preliminary results have been extended in several respects.

(i) *Recognition that a two-component analysis may be inadequate.*¹⁶ Although it can be concluded with some certainty that the rigid broad component has usually been shown to relate predominantly to the crystalline phase, the mobile component is often heterogeneous. Sometimes, as has been observed for oriented fibers, two 'narrow' components can be identified, and only in exceptional cases is the narrow component truly liquid-like with a Lorentzian lineshape.

(ii) *Attempts to produce quantitative lineshapes for the several components, especially the rigid crystalline phase.* In polyethylene and poly(vinylidene fluoride), the structure shows that the predominant intramolecular dipolar interaction arises from the pairs of protons attached to a carbon atom. It has been found very satisfactory^{17,18} to model the lineshape for the crystalline component as a Gaussian doublet [Figure 5], defined as

$$Y(\Delta B) = a_1 \left\{ \exp \left[-\frac{(\Delta B - a_2)^2}{2a_3^2} \right] + \exp \left[-\frac{(\Delta B + a_2)^2}{2a_3^2} \right] \right\} \quad (24)$$

This describes the superposition of two identical Gaussian lineshapes whose individual second moments about their

Figure 5 Proton NMR spectrum of polyethylene, obtained by Fourier transformation of FID following a solid echo pulse sequence. The solid line is the fit to equation (24), giving a crystallinity of 84%

centers are a_3^2 , separated by a field interval $2a_2$. The variable $\Delta B = B - B_0$, where B_0 is the magnetic field at the center of the doublet. The area under the curve can be shown to be $(8\pi)^{1/2}a_1a_3$, and the second and fourth moments are

$$\langle \Delta B^2 \rangle = a_2^2 + a_3^2 \quad (25)$$

$$\langle \Delta B^4 \rangle = a_2^4 + 3a_3^4 + 6a_2^2a_3^2 \quad (26)$$

A recommended procedure when the spectrum is composite in nature is to fit the outer part of the experimental spectrum with a_1 , a_2 , and a_3 as adjustable parameters, using a least-squares procedure with parabolic extrapolation,¹⁷ minimizing the sum

$$\chi^2 = \sum_i \frac{[A_i - Y(\Delta B_i)]^2}{\sigma_i^2} \quad (27)$$

where A_i is the experimental value of the absorption at the i th point and $Y(\Delta B_i)$ the corresponding value of the Gaussian doublet. χ^2 can be considered as a function of a_1 , a_2 , and a_3 represented by a three-dimensional hypersurface, which must be searched for the correct global minimum. This is ensured by choosing initial values for a_2 and a_3 by calculating the value of a_2 appropriate to the proton pair in the CH_2 group and then deriving a_3 from the theoretical second moment using $\langle \Delta B^2 \rangle = a_2^2 + a_3^2$. With these two parameters chosen, the choice of an initial value for a_1 could easily be made. For isotropic samples, Pranadi and Manuel¹⁷ showed that confirmation of the satisfactory nature of this fitting procedure can be obtained by comparing the ratio of the squares of the second moment to the fourth moment for the Gaussian doublets fitted to the theoretical value for an isotropic fully crystalline sample. For oriented samples, Clements et al.¹⁸ carried out the fitting procedures for different directions of $\mathbf{B}_0$ with respect to the sample symmetry axis (fiber symmetry), and showed that these led to very similar crystallinity values, and also that the values of $\langle P_2(\cos \Delta) \rangle$ and $\langle P_4(\cos \Delta) \rangle$ obtained in this way agreed well with these obtained from X-ray diffraction measurements.

Bergmann and Nawotki,¹⁹ and subsequently Kitamaru et al.,²⁰ have proposed that the spectra of isotropic semicrystalline polymers consist of three superimposed lines of different widths, although the narrow and intermediate lines are not separately resolved in the broadline spectrum. Both sets of workers obtained the lineshape for the broad crystalline component from the measured spectrum of a very highly crystalline linear polyethylene at a low temperature, correcting this for increases in lattice spacing at higher temperatures. The lineshape for the intermediate component was obtained from the spectrum calculated by Gutowsky and Pake²¹ for an isotropic assembly of proton pairs undergoing hindered rotation about the line joining them, and broadened by convolution with a Gaussian function. The narrow component was assumed to have a Lorentzian shape. Bergmann and his co-workers applied these procedures to many semicrystalline polymers, including poly(oxyethylene), poly(ethylene oxide), poly(vinylidene fluoride), Nylon 6 and polypropylene. Kitamaru and his colleagues concentrated their efforts on polyethylene, exploring the effects of molecular weight on both melt-crystallized and solution-crystallized materials. Kitamaru and Horii²² also reported measurements on oriented fibers where a three-component structure could be clearly identified (Figure 6). Similar results were reported by Smith et al.²³ for highly drawn polyethylene fibers, and an attempt was made

Figure 6 Three-component analysis at room temperature for fibers drawn to different degrees. The draw ratio (DR) is indicated. Dashed, dotted, and broken lines indicate narrow, medium, and broad components, respectively. Thick dotted and solid lines indicate the composite curve for the three components and the experimental spectrum, respectively. R. Kitamaru and F. Horii, *Adv. Polym. Sci.*, 1978, **26**, 137. © (1978) Springer-Verlag

to determine the orientation functions $\langle P_2(\cos \Delta) \rangle$ and $\langle P_4(\cos \Delta) \rangle$ for the intermediate component from the anisotropy of the second moment of this component on the assumption that this arises from oriented chains undergoing rotation about the chain axis.

A major disadvantage of the broadline CW technique (apart from the availability of suitable equipment) is the inevitable distortion of the linewidth due to the field modulation method of detection. Although correction procedures can be applied, these are least satisfactory for the narrowest components. There are therefore considerable incentives to use the latest NMR facilities and obtain the lineshape in the frequency domain, i.e., to measure the free induction decay (FID). In fact, attempts to interpret the FID for semicrystalline polymers appear to be more empirical and less quantitative than the CW studies described in detail above. Bergmann²⁴ has suggested decomposition of the FID into components: the crystalline component as a Gaussian multiplied by a sinc function (the 'Abragam function' proposed for the FID of CaF_2), and a Gaussian distribution of Kubo–Tomita functions to represent the remaining mobile regions (i.e., including at least two components analyzed from CW studies). Although useful empirical information has been obtained from this and similar procedures, it can only be concluded that this area is still unresolved.

3.2 High-Resolution Spectra

High-resolution ^{13}C measurements have also been shown to provide detailed information on the phase studies of semicrystalline polymers. Kitamaru and his colleagues²⁵ showed that for uniaxially oriented polyethylene films, two sharp lines were observed, which could be assigned to the crystalline and noncrystalline regions, respectively. The noncrystalline line was further resolved on the basis of spin–spin relaxation into two components—attributed to a true amorphous component and a crystalline–amorphous interface, respectively. The presence of three components was confirmed by lineshape analysis (Figure 7). Finally, it was concluded from selective relaxation experiments that the crystalline line is composed of three components with different spin–lattice relaxation times.

3.3 Longitudinal Relaxation T_1

The inversion–recovery method for measuring T_1 where the FID following a $180_y^\circ - \tau - 90_x^\circ$ pulse sequence is recorded can also be used to separate the components in a composite spectrum, and hence assist the decomposition procedures. Direct measurements of T_1 for protons do not generally show other than a single exponential decay owing to very efficient spin diffusion between protons.

3.4 Relaxation in the Rotating Frame; $T_{1\rho}$

Measurements of $T_{1\rho}$ have been used successfully to identify different phases and to provide new understanding of the role of spin diffusion as well as relating this to the dimensions of sample morphology (e.g. lamellar thicknesses). Packer and his colleagues²⁶ have made notable contributions to this subject.

4 RELAXATION PARAMETERS AND POLYMER DYNAMICS

One of the main areas of interest in the application of NMR to the study of solid polymers is in the relationship between the temperature dependence of the NMR relaxation times and the locations and activation energies of transitions observed by dynamic mechanical and dielectric relaxation studies. The advantage of NMR in this respect is that it can help identify the precise molecular origin of polymer transitions. This is particularly true for isotopically labeled structures, and in the case of high-resolution ^{13}C studies, where as a result of the chemical shift, and the absence of spin diffusion effects, the relaxation times of chemically distinct carbons can be measured.

4.1 Relaxation Theory

Let us take as a starting point the expression for T_1 derived by Bloembergen, Purcell and Pound,²⁷ as modified by Kubo and Tomita,²⁸ written here for homonuclear dipolar interactions between protons:

$$\frac{1}{T_1} = \frac{3}{20} \left(\frac{\mu_0}{4\pi} \right)^2 \gamma^4 \hbar^2 \sum_j r_j^{-6} [J(\omega_0) + 4J(2\omega_0)] \quad (28)$$

where $J(\omega)$ is the spectral density, which is obtained by considering a single exponential autocorrelation function, followed by a Fourier transformation, as follows:

$$G(t) = \exp\left(-\frac{t}{\tau_c}\right) \quad (29)$$

$$J(\omega) = \int_{-\infty}^{\infty} G(t) \exp(-i\omega t) dt \quad (30)$$

This leads to an expression containing a single correlation time τ_c :

$$\frac{1}{T_1} = \frac{3}{10} \left(\frac{\mu_0}{4\pi} \right)^2 \gamma^4 \hbar^2 \sum_j r_j^{-6} \left(\frac{\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{4\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right) \quad (31)$$

It will be more convenient to write this in a form containing the isotropic second moment M_2 , written here in frequency units, such that

$$\frac{1}{T_1} = \frac{2M_2}{3} \left(\frac{\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{4\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right) \quad (32)$$

The shortcomings of considering a single correlation time will be addressed in due course. For now, however, this assumption is more useful for illustrating the general features of relaxation behavior than considering the additional complexities introduced by a distribution of correlation times, at this stage. As illustrated in Figure 8, equation (32) predicts T_1 to pass through a minimum, and this occurs when $\omega_0 \tau_c$ is approximately 0.62.

On the long- τ_c side of the minimum, T_1 decreases with decreasing τ_c (or increasing temperature), and this will generally be the case for a solid polymer. The observation of a minimum in the T_1 plot is then taken as a good indication of the onset of a mechanical transition, which would be observable by a drop in the dynamic storage modulus, or by a peak in the loss modulus or damping factor in, say, a dynamic mechanical experiment. However, the frequency of the NMR T_1 measurement will be in the region of hundreds of megahertz, and this presents at least two problems. First, the nature of the polymer chain motion at such high frequencies may well be different from the motion at the lower frequencies (Hz–kHz) encountered in dynamic mechanical and dielectric analysis. Second, depending on the activation energy of the

Figure 8 Dependence of T_1 , T_2 , and $T_{1\rho}$ on correlation time τ_c for frequencies $\omega_0/2\pi = 100$ MHz and $\Omega_1/2\pi = 40$ kHz. Reprinted by permission from R. K. Harris, Nuclear Magnetic Resonance Spectroscopy, Revised reprint, Longman. © (1986) Robin K. Harris

process, to observe the transition at megahertz frequencies may require prohibitively high temperature. As a result, it is usually more rewarding to study the temperature dependence of $T_{1\rho}$. The relaxation rate as a function of τ_c is obtained in a similar manner to before, and the expression, again for a single τ_c , is given by

$$\frac{1}{T_{1\rho}} = \frac{M_2}{3} \left(\frac{3\tau_c}{1 + 4\Omega_1^2 \tau_c^2} + \frac{5\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{2\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right) \quad (33)$$

Ω_1 is now the strength of the B_1 spin locking field in the on-resonance rotating frame. This frequency is usually at least three orders of magnitude less than the Larmor frequency ω_0 applicable to T_1 relaxation. The dependence of $T_{1\rho}$ on τ_c is similar to that of T_1 (Figure 8), but the consequence of the lower-frequency measurement is that the minimum appears at much higher correlation times, and therefore at lower, more accessible, temperatures. For completeness, the dependence of T_2 is also shown, and the relevant expression is given by

$$\frac{1}{T_2} = \frac{M_2}{3} \left(3\tau_c + \frac{5\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{2\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right) \quad (34)$$

The dominant contributions to T_2 in solids arise from the frequency-independent term, and so the temperature at which a transition is indicated, by an increase in T_2 , is not usually affected by the NMR frequency,²⁹ at least at frequencies corresponding to the linewidth, in hertz. Analogous expressions to those above can be obtained for heteronuclear interactions,³⁰ pertaining to, for example, ^{13}C relaxation.

4.2 Calculation of the Activation Energy

The frequency dependence of the glass transition in polymers is usually best described by the Williams–Landel–Ferry equation (WLF), or its close equivalent, the Vogel–Fulcher–Tammann (VFT) equation:

$$\tau_c = \tau_0 \exp \left(\frac{B}{T - T_0} \right) \quad (35)$$

where B is related to the activation energy and T_0 is a reference temperature equal to $T_g - C_2$, where C_2 is the WLF constant. On the other hand, minor local relaxations and transitions often conform to the Arrhenius equation, such that

$$\tau_c = \tau_0 \exp \left(\frac{E}{RT} \right) \quad (36)$$

where E is the activation energy. An inspection of the plots in Figure 8 shows that, beyond a certain displacement either side of the T_1 or $T_{1\rho}$ minimum, the plot of $\ln T_1$ or $\ln T_{1\rho}$ versus $\ln \tau_c$ is linear. A combination of this observation with equation (36) suggests that a plot of $\ln T_1$ or $\ln T_{1\rho}$ versus T^{-1} should yield a straight line of slope $+E/R$ or $-E/R$, corresponding to the long τ_c or short τ_c sides of the minimum, respectively. Of course, for T_g behavior, the relevant abscissa would be $(T - T_0)^{-1}$. Now, it is usually the case that activation energies

Table 1 Correlation Time (τ_c) Relationships, and the Range of τ_c Appropriate to Each Measurement (Adapted from V. J. McBrierty and D. C. Douglass, *J. Polym. Sci., Macromol. Rev.* 1981, **16**, 295. © (1981) John Wiley & Sons, Inc. Reprinted with permission)

NMR feature	Expression for τ_c (s)	Range of τ_c (s)
T_1 minimum	$(\sqrt{\omega\omega_0})^{-1}$	4×10^{-8} – 4×10^{-10}
$T_{1\rho}$ minimum	$(\gamma B_1)^{-1}$	2×10^{-5} – 3×10^{-7}
T_2 transition	T_{2LT}^a	2×10^{-5} – 2×10^{-6}
Linewidth transition	$(\gamma\delta H_{LT})^{-1b}$	2×10^{-5} – 2×10^{-6}

^a $T_{2LT}^{-2} = T_{2lt}^{-2} - T_{2ht}^{-2}$, where T_{2lt} and T_{2ht} are the values of T_2 on the low- and high-temperature sides of the transition.

^b δH_{LT} is the linewidth between points of inflection.

calculated by this method are much smaller, typically by an order of magnitude, than those calculated from dielectric or dynamic mechanical data. The source of this discrepancy lies in the distribution of correlation times, which will be addressed shortly. However, a means of avoiding this difficulty has been discussed by McBrierty and Douglass.³¹ They point out that the positions of the minima in T_1 and $T_{1\rho}$ plots, or points of inflection in the case of T_2 and linewidth changes, are unaffected by the correlation time distribution. A value for τ_c associated with each of these features can be determined using Table 1, and the activation energy again calculated by applying equation (36).

Another similar method is to use the temperatures of T_1 and $T_{1\rho}$ minima obtained at a number of different B_0 and B_1 field strengths. However, it is difficult in practice to use more than a couple of different B_0 fields, and the experimental range of B_1 field strengths that can be used in a $T_{1\rho}$ experiment is limited, since the amplitude of B_1 must be larger than the frequency spread in the spectrum of the spin system.³² The upper limit will be dictated by probe stability, so these considerations would typically restrict the B_1 field strength to the range 20–80 kHz, which is rather a small range for the purposes of activation energy calculations.

4.3 The Distribution of Correlation Times

As mentioned earlier, the assumption of a single correlation time leads to much smaller activation energies than those calculated from other methods. Connor³³ has discussed an approach whereby the expression for T_1 , equation (32), can be modified to embrace a continuous distribution of correlation times, described by a normalized density function $H(\tau)$, to give

$$\frac{1}{T_1} = \frac{2M_2}{3} \left[\int_0^\infty \frac{\tau_c H(\tau_c) d\tau_c}{1 + \omega_0^2 \tau_c^2} + 4 \int_0^\infty \frac{\tau_c H(\tau_c) d\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right] \quad (37)$$

Schaefer³⁴ has analyzed solution and solid state ^{13}C NMR relaxation times and has devised a log χ^2 distribution function to fit the experimental data, with reasonable success. Several other empirical distribution functions have been suggested, mainly to fit dielectric relaxation data, which can then be extended to NMR. The procedure involves introducing a distribution function $H(\tau_D)$, where τ_D is the correlation time appropriate to dielectric loss, and is related to the NMR

correlation time via $\tau_D \approx 3\tau_c$. If τ_0 is the center of the distribution on a logarithmic timescale then we define another parameter s such that

$$s = \ln \left(\frac{\tau_D}{\tau_0} \right) \quad (38)$$

$H(\tau_D)$ is now replaced by another function $F(s)$, where

$$\tau_D H(\tau_D) = F(s) \quad (39)$$

Several forms of the function $F(s)$, such as Gaussian, Fuoss–Kirkwood and Cole–Cole have been suggested,³³ and used to fit dielectric relaxation data with varying degrees of success. The same functions can then be employed to fit the T_1 data, by substitution into equation (37) and subsequent integration. However, the extension of this approach to the expressions for $T_{1\rho}$ and T_2 is more complex, and so these distribution functions will not be considered further here. The exception to this is the Cole–Davidson function,³³ which is potentially more useful, since it accommodates the possibility of an asymmetric distribution, and is more amenable to extension to $T_{1\rho}$ data. This function is given by

$$F(s) = \begin{cases} \frac{\sin \delta \pi}{\pi} (1 - e^{-s})^{-\delta} & (\tau_c < \tau_0) \\ 0 & (\tau_c > \tau_0) \end{cases} \quad (40)$$

where δ is an adjustable parameter quantifying the width of the distribution. This leads to the following expression for T_1 :

$$\frac{1}{T_1} = \frac{2M_2\delta}{3} \left[\frac{\tau_c}{(1 + \omega_0^2 \tau_c^2)^{\delta/2} (1 + \delta^2 \omega_0^2 \tau_c^2)^{1/2}} + \frac{4\tau_c}{(1 + 4\omega_0^2 \tau_c^2)^{\delta/2} (1 + 4\delta^2 \omega_0^2 \tau_c^2)^{1/2}} \right] \quad (41)$$

Extension of this to the expression for $T_{1\rho}$ is obvious. Calculation of the activation energies can be done in the same manner as before, by taking the slope of the $\ln T_1$ or $\ln T_{1\rho}$ versus T^{-1} plot in the linear region. Now, however, the slope of the low-temperature side of the plot depends on the width parameter δ , having the value $+E/R$, but the consequence of the asymmetry is that the high-temperature slope is unaffected, and is $-E/R$, as for the single- τ_c case.

More recently, a different and potentially more useful approach has appeared. This is the use of Williams–Watts stretched exponential correlation function,³⁵ again borrowed from dielectric relaxation studies, which has the form

$$G(t) = \exp \left[\left(\frac{-t}{\tau_c} \right)^\beta \right] \quad (42)$$

The stretched exponential representation is finding increasing use in studies by a number of experimental techniques of a whole range of glass-forming systems, including solid polymers, and the value of β obtained from the fit is used to classify materials in terms of ‘strong’ and ‘weak’ glasses. Garroway et al.³⁶ have used this formulation to interpret changes in the lineshape of ^{13}C in phenylene with temperature

Figure 9 Proton T_1 and $T_{1\rho}$ versus inverse temperature for chloral polycarbonate. The solid lines are fits to the stretched exponential correlation function. Reprinted with permission from A. A. Jones, J. F. O'Gara, P. T. Inglefield, J. T. Bendler, A. F. Yee, and K. L. Ngai, *Macromolecules*, 1983, **16**, 658. © (1983) American Chemical Society

in epoxy resins, using a value for β of 0.3. Roy et al.³⁷ also found this value of β in their study of phenylene ring flips in poly(butylene terephthalate) using deuterium NMR. Jones and co-workers³⁸ have used the stretched exponential to interpret the temperature dependence of the proton T_1 and $T_{1\rho}$ in polycarbonate, through the sub- T_g transition. The procedure is to obtain the spectral density $J(\omega)$ by a Fourier transformation of equation (42) [compare with equation (29)] and substitute it into the appropriate expressions for T_1 and $T_{1\rho}$, equations (32) and (33). Two B_0 field strengths were used (90 and 20 MHz), and the B_1 field strength was 43 kHz. As shown in Figure 9, the fit to any one set of data is adequate rather than spectacular, but what is impressive is that the same value of β (0.2) was used to fit the data at all three frequencies. More recently, Colmenero et al.³⁹ used this procedure to fit ^{13}C T_1 and $T_{1\rho}$ relaxation times with temperature, in a study of the glass transition in poly(vinyl methyl ether). The NMR data were complemented with dielectric, dynamic mechanical, and neutron scattering studies, and a universal value of $\beta = 0.44$ was found. It would appear, then, that the stretched exponential representation of the correlation time distribution in polymers will prove to be the method of choice in future.

5 POLYMER NETWORKS AND CHAIN ENTANGLEMENTS

Above the glass transition temperature, or above the melting temperature in the case of semicrystalline materials, polymers whose chains are below the molecular weight necessary for entanglement formation (M_e) are best described

as viscous liquids. Above M_e , polymers display a temporary rubber-elastic behavior as a direct consequence of the formation of an entanglement network. If permanent chemical cross-links are also incorporated into the structure, polymers in this temperature regime become true rubbers, with the elastic behavior characterized by contributions from the permanent cross-links, and the chain entanglements trapped between them. The rheological and mechanical properties of polymers in this state have been extensively studied,⁴⁰ and the theoretical description of the chain dynamics contributing to the permanent and temporary rubber-elastic behavior is now quite well advanced.⁴¹ NMR studies of the dynamics have also been carried out, although perhaps less extensively, and recently a theoretical understanding has begun to emerge.

5.1 Experimental Considerations

The most common experiment for studying the dynamics of polymer melts by NMR is the observation of the proton transverse relaxation behavior. The shape and the rate of decay of the transverse magnetization are dictated by the residual dipolar interactions between protons that are not averaged to zero by molecular motion. The transverse relaxation can, in principle, be described by the FID following a 90° pulse. However, the inevitable B_0 field inhomogeneity causes different protons to have slightly different Larmor frequencies, and this contributes to a dephasing of spins in the x - y plane that shortens the FID significantly for liquid-like signals. A commonly used technique to overcome this problem is the Carr-Purcell-Meiboom-Gill⁴² (CPMG) echo train: $90^\circ - (\tau - 180^\circ - \tau - \text{echo})_n$. This is illustrated in Figure 10. After the initial 90° pulse, the magnetization is allowed to decay for a time τ (which is long compared with the pulse width), and then subjected to a 180° pulse. The result is that the magnetization is then refocused, forming an 'echo' at a time τ later. The magnitude of successive echoes then forms the true FID. A preferred refinement to this is the Levitt-Freeman⁴³ modification, which is the sequence $90_x^\circ - \tau - (90_x^\circ - 180_y^\circ - 90_x^\circ - 2\tau)_n$. This is a self-compensating pulse sequence that corrects for any slight error in the pulse widths by ensuring that every second echo is correct, providing that diffusional processes are not significant.

5.2 Interpretation of the FID from Polymer Melts

5.2.1 Phenomenological Features

For low molecular weight polymers, the FID tends to be a single exponential, characterized by a time constant T_2 , the spin-spin relaxation time. The magnitude of T_2

Figure 10 The CPMG pulse sequence for measuring the transverse relaxation function

Figure 11 Transverse relaxation functions for monodisperse polyethylenes. (a) Molecular weights below the entanglement point: Δ , 342; +, 525; $\circ$, 900; $\square$, 1700 g mol⁻¹. (b) Showing the transition from unentangled to entangled chains: Δ , 5700; +, 11 400; $\circ$, 30 600; $\square$, 55 700; $\bullet$, 107 000 g mol⁻¹. decreases as the molecular weight increases, until M_e is reached, and the decay is no longer simply exponential. This effect is illustrated in Figure 11 for samples of monodisperse polyethylene. Cross-linked polymer networks show the same general features as highly entangled systems, and a phenomenological interpretation of the FID was provided by Charlesby and co-workers in a number of papers.^{44,45} They described the FID for irradiated (and therefore cross-linked) poly(dimethylsiloxane) (PDMS) in terms of two exponential components, characterized by two time constants T_{2S} and T_{2L} , referring to the short and long relaxation times, respectively, such that

$$\frac{I(t)}{I(0)} = f \exp\left(-\frac{t}{T_{2S}}\right) + (1 - f) \exp\left(-\frac{t}{T_{2L}}\right) \quad (43)$$

It is found that f corresponds well to the gel fraction obtained by extraction techniques, with T_{2S} being directly proportional to the number average molecular weight between cross-links,⁴⁵ M_c , and T_{2L} related to the M_n of the chains forming the sol fraction. This approach can also be extended to entanglement networks, where now T_{2S} is related to the

entanglement density manifested at a particular temperature. On the timescale of the NMR experiment, then, this suggests that some entanglements will appear to be static. Charlesby has shown that this is similar and indeed related to the observation of the plateau modulus in dynamic shear experiments.⁴⁶

5.2.2 Theories Based on Scale-Invariant Models

5.2.2.1 The Cohen-Addad NMR Submolecule. Although extremely useful for the characterization of polymer networks, the preceding analysis has little theoretical basis. In this respect, a more satisfactory description is given by the work of Cohen-Addad,⁴⁷ who developed a scale-invariant model of the polymer chain by application of the submolecule concept. This is based on the idea that the whole relaxation time spectrum of polymer chains in the melt must consist of two well-separated dispersions Ω_1 and Ω_2 . The Ω_1 spectrum is associated with high-frequency relaxation processes of short segments within a submolecule, which comprises a number N_a of monomer units, typically about 10, each of step length a . Each bond is considered to carry a proton pair, of separation b , and interactions between proton pairs are neglected. The set Ω_2 of long relaxation times characterizes the long-range configurational changes, involving several submolecules and motions beyond entanglements. Under these conditions, the transverse relaxation function $G(t)$ is given by

$$G(t) = \exp\left(-\frac{t}{T_2}\right) \left\{ \frac{1 + 3\theta^2 + [(1 + 3\theta^2)^2 + 4\theta^6]^{1/2}}{2[(1 + 3\theta^2)^2 + 4\theta^6]} \right\}^{1/2} \quad (44)$$

where $\theta = \frac{1}{3}t(M_2^M)^{1/2}$, M_2^M being the second moment associated with the residual spin coupling interactions induced by entanglements, and is given by

$$M_2^M = \frac{0.6M_2^G}{N_a^2} = \frac{0.27\gamma^4\hbar^2}{N_a^2b^6} \quad (45)$$

where, in turn, M_2^G is the rigid-lattice second moment. At long times, $G(t)$ varies as $\theta^{-3/2}$, not the exponential function of simple T_2 behavior. Equation (45) was fitted to experimental data on highly entangled PDMS chains in high concentration in chloroform solution,⁴⁷ and from the fit a molecular weight between chain entanglements of 8224 g mol⁻¹ was obtained, comparing well to the value of 8100 g mol⁻¹ determined from viscoelastic measurements.

5.2.2.2 The Hierarchical Brereton Model. More recently, Brereton⁴⁸⁻⁵¹ has produced an exact expression for the transverse relaxation function, using a similar scale-invariant model to Cohen-Addad. Considering dipolar interactions within a proton pair separated by a distance d leads to the following expression for $G(t)$:

$$G(t) = \left\langle \cos \left\{ \delta \int_0^t [3 \cos^2 \alpha(t') - 1] dt' \right\} \right\rangle \quad (46)$$

where $\alpha(t')$ is the angle the internuclear vector $\mathbf{d}$ makes with the static magnetic field $\mathbf{B}_0$, and δ is given by

$$\delta = \frac{3\gamma^2\hbar}{4d^3} \quad (47)$$

We now again consider a submolecule, of length b , comprising N_a repeat units, making an angle θ with respect to $\mathbf{B}_0$, leading to

$$G(t) = \left\langle \cos \left[\frac{3\Delta}{b^2} \int_0^t (2z^2 - x^2 - y^2) dt' \right] \right\rangle \quad (48)$$

where Δ is a rescaled dipolar interaction, given by

$$\Delta = \frac{3}{2} \frac{\gamma^2 \hbar}{N_a d^3} \quad (49)$$

If N_a is large then x , y and z are independent and can be described by the following Gaussian random time process:

$$g(\Delta, t) = \left\langle \exp \left(\frac{3\Delta i}{2b^2} \int_0^t x^2(t') dt' \right) \right\rangle \quad (50)$$

and then

$$G(t) = \text{Re}[g(2\Delta, t)g(-\Delta, t)g(-\Delta, t)] \quad (51)$$

Equation (51) can be solved to give a functional form of $G(t)$ for different levels of dynamics. For molecular weights less than M_e , we consider fast dynamics appropriate for a Rouse chain⁴⁸ consisting of N submolecules. $G(t)$ is then predicted to be a single exponential:

$$G(t) = \exp \left(-\frac{6\Delta^2 \tau}{\pi} \ln N t \right) \quad (52)$$

where τ is the fastest relaxation time for the smallest length, corresponding to one submolecule. Experimentally, of course, we associate the spin-spin relaxation time with the single exponential, such that $G(t) = \exp(-t/T_2)$. Equating this to equation (52) leads to the relationship

$$\frac{1}{T_2} = \frac{6\Delta^2 \tau}{\pi} [\ln M_n - \ln(mN_a)] \quad (53)$$

where M_n is the molecular weight of the chain, and m the molecular weight of a repeat unit. It is apparent from equation (53) that a plot of the relaxation rate $1/T_2$ versus $\ln M_n$ should be linear, allowing the parameters N_a , Δ , and τ to be determined from the slope, intercept, and equation (49). For the polyethylene data⁴⁹ shown in Figure 12 this plot is indeed linear up to M_e , and it is found that N_a , the number of monomer units in a submolecule (in this case, the Rouse unit), is 9.0, and the fastest Rouse relaxation time is 1.49×10^{-8} s.

Similar studies have also been undertaken on polyethylene oxide, a much more highly coiled and flexible chain, and here it is found that N_a is correspondingly smaller, at only 1.5 repeats. The onset of entanglement formation is indicated in Figure 12 for polyethylene by the departure from the linearity expressed by equation (53). At this point, the FID is no longer a single exponential, and the characterization of the decay by T_2 has no real meaning. However, for the purposes of indicating this departure from fast dynamics, T_2^* has been plotted, which is simply the time taken for the magnetization to decay to e^{-1} of its original value. With the onset of entanglement formation,

Figure 12 T_2^{-1} versus $\ln M_n$ for monodisperse polyethylenes. The solid line is the fit to the Rouse chain model, equation (53). The point marked E represents the onset of entanglements. we encounter the next level in the hierarchical model,⁴⁹ shown in Figure 13.

We now have a number N_b of our submolecules spanning entanglement points, defining a vector $\mathbf{R}$. In the model, the Rouse dynamics is retained for each of the $\mathbf{b}$ bonds, and $\mathbf{R}$ is considered to be a reptating chain with a single relaxation time T_R , related to the bond correlation function:

$$\frac{\langle R_i(t) R_i(0) \rangle}{\langle R^2 \rangle} = \exp \left(-\frac{t}{T_R} \right) \quad (54)$$

The full expression for $G(t)$ is obtained by numerical evaluation of the following product formula:

$$g(\Delta, t) = \prod_{\alpha} [1 - 3it\Delta_{\alpha}(t)]^{-1/2} \quad (55)$$

where α is an integer variable and $\Delta_{\alpha}(t)$ is related to the bond correlation functions. As can be seen from Figure 11(b),

Figure 13 Illustration of the Brereton model, showing two structural levels: the atomic bonds forming one $\mathbf{b}$ vector, and the $\mathbf{b}$ vectors constituting the larger $\mathbf{R}$ vectors

the model provides good fits to the polyethylene data above the entanglement point.⁴⁹ From these fits, the average number of b bonds in the R chain is 25. Combining this with the number of monomer units in the b bond leads to a value of 6300 g mol^{-1} for M_e , which compares well to results from viscoelastic studies of polyethylene at the same temperature (149°C), and with the departure from linearity of the FIDs. Furthermore, the plot of $\ln T_R$ versus $\ln M_n$ is linear, and of slope 3.5, in other words $T_R \propto M_n^{3.5}$, which is consistent with viscoelastic relaxation data on polymer melts in the entangled regime. A detail of the fitting procedure for the entangled polymers is that a small fraction of free chain ends needs to be invoked to accommodate the exponential tail of the FID at long times. In general, the fraction of free ends obtained from the fit is consistent with that expected from the molecular weight of the chain and the entanglement density.

5.2.3 The Effect of Deformation

Brereton⁵¹ has developed the model to incorporate the effect of permanent chemical cross-links and the effect of deformation. Here, the cross-links are permitted a certain fluctuation volume, which is considered to be strain-dependent, the fluctuations increasing in the direction of strain. Other notable contributions to the study of network deformation by NMR have been made by Sotta and Deloche.^{52,53} They have studied the deuterium NMR of deuterated PDMS networks,⁵² and of deuterated linear 'probe' polymer chains within networks.⁵³ In both cases, they have observed a line splitting of the order of 100 Hz, which increases with deformation, and is attributed to the residual quadrupolar interactions induced by uniaxial orientational order in the network. Recently, however, Brereton⁵¹ has reinterpreted these data, and attributed the line splitting to the cross-link fluctuations.

1 INTRODUCTION

Synthetic polymers undergo organic and inorganic reactions just like their low molecular weight counterparts. Many of these reactions are commercially important, leading to modified polymers with improved properties. Included in this category are chlorination and bromination reactions, irradiated polymers, functionalization, and cross-linking reactions. Many thermosetting polymers need to be cured during or after polymerization. Some high-performance materials (e.g., ceramics and carbon fibers) are formed by heating the precursor polymers in controlled atmospheres at high temperatures. Not all polymer reactions are desirable; for example, oxidative and degradative processes tend to degrade the polymer properties, and should be controlled.

In many of these processes, NMR has been used as a characterization technique. If the polymers involved are soluble, studies using liquid state NMR are usually preferred. In many reactions (e.g., cross-linking, curing, and pyrolysis), the resulting polymers are insoluble or partially soluble. In these cases, solid state CP MAS techniques can be used to give chemical information. In many cases, nuclear relaxation times alone (especially T_2) can provide very useful information.

Because of the scope of the published literature, this article will selectively review the major types of polymer reactions as studied by NMR. Space limitations necessitate the exclusion of polymer/polymer transformations, metal chelation, graft copolymerization, polymer blending, biodegradable processes, and reactions involving cellulose.

2 OXIDATION REACTIONS

The oxidative degradation of polymers is of major industrial importance. Almost all commercial polymers undergo oxidation with time, and have to be stabilized with antioxidants and antiozonants. Sometimes, oxidation is carried out deliberately in order to provide a more polar polymer surface. The major oxidation pathways (Scheme 1) are fairly well understood.¹

Scheme 1

Scheme 1 is valid for saturated polymers like polyethylene and polypropylene. Many of the mechanistic studies have been carried out using IR (see, e.g., Adams²). Liquid state ^{13}C NMR has been shown^{3,4} to give detailed information on polyethylene oxidation. The ^{13}C NMR spectra of low-density polyethylene (LDPE) and oxidized LDPE³ are given in Figure 1. The oxidized sample gives many resonances, from which hydroperoxide, alcohol, ketone, acid, peracid, ester, and γ -lactone can be clearly identified.

When the oxidation process is carried out over time, the distribution of these various oxidation products changes. A plot of concentration versus time is shown in Figure 2.³ As expected, the hydroperoxide forms in the early phase of oxidation. At the oxidation temperature employed (140°C), hydroperoxide is unstable and degrades in time to the other oxidation products. At very high levels of oxidation, acids and ketones are the major products.

A similar NMR study of the oxidation of natural rubber has been carried out by Golub et al.⁵ The main difference with polyethylene is the ready formation of hydroperoxide and peroxide (owing to the reactivity of the allylic hydrogen) and the occurrence of epoxide. Studies have also been conducted on the photooxidation^{6a,6b} and thermal oxidation^{6c} of polybutadiene using NMR and other analytical techniques, and on other oxidized polymeric systems.⁷

3 CHLORINATION AND BROMINATION

The chlorination reaction is often carried out on hydrocarbon polymers and poly(vinyl chloride). The NMR spectra are

Figure 1 ^{13}C NMR spectra (at 25 MHz) of LDPE before oxidation (a), and after oxidation (b), (c). The oxidation products are identified by numbers as follows: 1, ketone; 2, acid; 3, secondary hydroperoxide; 4, secondary alcohol; 5, ester of acid and secondary alcohol; 6 = γ -lactone.³ The designations α , β , γ refer to the carbons located at α , β , γ away from the functionality, and C* is the carbon bonded to oxygen. In 5 and 6, the carbons attached to O through σ bonds are 5C $_0$ and 6 γ , respectively. (Reproduced by permission of the American Chemical Society)

typically very complex, frequently with multiple resonances and broad, nondescript spectral features. For example, the ^{13}C NMR spectra⁸ of chlorinated polyethylene and chlorinated polyisoprene are given in Figure 3.

The chemical structure of chlorinated polyethylene has been much studied using NMR.^{9–13} The chlorination reaction occurs in a stepwise fashion, starting with $-\text{CH}_2-$ (designated 0), and generating $-\text{CHCl}-$ (designated 1) and $-\text{CCl}_2-$ (designated 2). Some reactions are shown in Scheme 2. The ^{13}C spectral assignments (primarily from Hösselbarth et al.¹³) are given in Figure 3(a).

The chlorination of polyisoprene is inherently a more complex reaction, but it gives a deceptively simple spectrum.^{8,14,15} Eskina et al.¹⁵ recently carried out a detailed NMR study of this reaction. They identified the main reaction pathways, pointing out the presence of linear reaction products and five-membered ring structures. Their results have been incorporated in Scheme 3. In view of their work, the ^{13}C NMR spectrum [shown in Figure 3(b)] can be interpreted⁸ on the basis of

Figure 2 Distribution of oxidation products of polyethylene as a function of the extent of oxidation (lower scale: O $_2$ absorbed; upper scale: time of reaction).³ (Reproduced by permission of the American Chemical Society)

two main structures. The linear product (1) has been assigned previously by Eskina et al.¹⁵ The five-membered cyclic product (2) was assigned⁸ on the basis of empirical additive shift rules.^{16,17}

Other NMR studies have been reported for chlorinated polypropylene,^{18,19} chlorinated ethylene/propylene copolymer,²⁰ chlorinated polybutadiene,²¹ and chlorinated poly(vinyl chloride).^{13,22–24} Keller and co-workers^{10,13,18,19} have made the most detailed studies of chlorinated polymers using ^{13}C NMR. For example, a series of spectra of chlorinated polypropylene¹⁸ showing an increasing level of chlorination is given in Figure 4. Using a large number of model compounds, Keller et al.¹⁸ devised general shift rules and made rather detailed assignments.

Bromination has been used to functionalize polymers and to improve their flame-retardant properties. For example, hydrobromination²⁵ has been performed on natural rubber, and has been studied using ^{13}C NMR. Polystyrene has been brominated to give a flame-retardant polymer. Under the reaction conditions, bromination occurs on the benzene ring, and has been studied by NMR.^{26–28} Other NMR studies include those of brominated poly(arylene ether sulfone),²⁹ a brominated copolymer of styrene and 2,6-dimethyl-1,4-phenylene oxide,³⁰ and brominated diacetylene.³¹

4 IRRADIATION

Irradiation with electrons or γ -rays is often used to improve the rheological behavior of polyolefins. In general, two reactions compete: cross-linking and chain scission. In polyethylene, cross-linking is the dominant reaction; in polypropylene, both reactions occur.

NMR studies of the irradiated polymers are difficult because the concentrations of the chemical species formed as a result

Figure 3 ^{13}C NMR spectra at 90 MHz of (a) chlorinated polyethylene (0, CH_2 ; 1, CHCl ; 2, CCl_2 ; groups being assigned are underlined) and (b) chlorinated polyisoprene. The spectrum can be assigned to two main structures: a linear product L_i (1), where $i = 1, \dots, 5$, and a cyclic product C_i (2), where $j = 1, \dots, 10$ (hydrogens are omitted for simplicity)

of irradiation are usually very low. One approach, successfully used by a number of workers,^{32–34} is to monitor the T_2 values on bulk polymers. With irradiation, a short relaxation time component is formed owing to decreased mobility. As expected, the amount of this short T_2 component increases with increasing irradiation. Charlesby and co-workers^{32,33} have carried out extensive studies of irradiated polyethylene, polyisoprene, poly(dimethylsiloxane), poly(ethylene oxide),

polyisobutylene, and polyacrylamide. An example of irradiated aqueous polyacrylamide³³ is shown in Figure 5.

Direct observation of the chemical structure of irradiated polymers can be achieved using liquid state NMR in some cases. Through the use of high radiation doses, and sometimes with model compounds, it is possible to identify the major structures. This is the case with polyethylene.^{35–39} Structures identified include internal olefins, saturated end groups, vinyl

4 POLYMER REACTIONS

Scheme 2

end groups, short branches, H-shaped cross-links, and Y-shaped branches.

Several studies have been carried out on irradiated polypropylene.^{40–42} The following observations have been made.

1. The tacticity of isotactic polypropylene decreases after irradiation.^{40,41}
2. Vinyl and saturated chain ends are formed through chain scission.^{41,42}
3. There is an increase in the number of head-to-head and tail-to-tail structures.⁴²
4. Although cross-linked structures are expected in this system, NMR evidence for them has been suggestive rather than definitive.⁴²

5 FORMATION OF FUNCTIONALIZED POLYMERS

Polymers are often reacted in order to place a special functional group or functional groups on the polymer chain. NMR has been used routinely to monitor the extent of the functionalization.

As an example, Rengarajan et al.⁴³ studied polypropylene that had been adducted with maleic anhydride using peroxide. The maleic functionality was detected at 175 ppm via solid state ¹³C NMR, but was not seen by liquid state NMR. Structure (3) previously proposed from FTIR data,⁴⁴ was confirmed.

Aglietto et al.⁴⁵ studied high-density polyethylene (HDPE) adducted with diethyl maleate. The maleate signals were observed directly as multiple resonances at 172–179 ppm through liquid state ¹³C NMR. A number of model compounds were used for spectral assignments. The authors concluded that structure (4) was found in the functionalized polymer.

1. Linear products

2. Cyclic products

Scheme 3

In a related study, Aglietto et al.⁴⁶ introduced isolated CH_2COOEt units onto polyethylene using ethyl diazoacetate, and characterized the polymer structure using ¹³C NMR.

Another reaction attracting attention is the dichlorocarbene addition of 1,4-polybutadiene.^{47–50} Other recent examples of functional polymers include those arising from the nucleophilic substitution reaction of poly(vinyl chloride) with sodium benzenethiolate and related compounds,^{51,52} from the addition of styrene onto the backbone of poly(methylsiloxane),⁵³ from the reaction of ethanolamine with poly(methyl acrylate),⁵⁴ and from the reaction of formaldehyde with polyamide.⁵⁵

6 CROSS-LINKING REACTIONS

Cross-linking by irradiation has been discussed in Section 4. Chemical means of cross-linking are exemplified by cross-

Figure 4 ^{13}C NMR spectra at 22.6 MHz of chlorinated polypropylene with different chlorine content G_α and degree of chlorination α .¹⁸ (Reproduced by permission of *Acta Polymerica*)

linked poly[(chloromethyl)styrene], studied by liquid state ^{13}C NMR.⁵⁶ Another important reaction pertains to elastomers, where cross-linking by sulfur and peroxide is commonly practiced. Solid state ^{13}C NMR has been used extensively,⁵⁷ primarily by Koenig et al. Sulfur vulcanization can also be followed by T_2 measurements.⁵⁸ Continuous wave ^1H NMR has been carried out⁵⁹ on swollen polymers to determine the extent of cross-linking in vulcanized polymer blends.

7 HEAT DEGRADATION AND PYROLYSIS

Upon heating in a controlled atmosphere, polymers undergo thermal reaction and (at higher temperatures) pyrolysis. Both liquid and solid state NMR can be used to study these reactions. For example, polyisoprene⁶⁰ and polybutadiene^{60,61}

Figure 5 T_2 and intrinsic viscosity $[\eta]$ of aqueous polyacrylamide (20% solution) as a function of irradiation dose. T_2 was measured on the ^1H signal at 90 MHz. D_g is the dosage when the polymer gels.³³ (Reproduced by permission of Elsevier)

will undergo cyclization reactions to form fused ring structures [see equation (1)], and will also depolymerize. NMR has been used to follow the degradation of poly(vinyl chloride) to form polyenes,⁶² polyacrylonitrile to form a ladder polymer,^{63–65} and polyacrylamide and acrylamide copolymers to form cyclic imides;^{66,67} see equations (2), (3), and (4), respectively.

In the above examples, the reactions are not as clean as depicted, and many reaction pathways are involved, with different products identified.

Recent degradation studies include thermal degradation of polychloroprene,⁶⁸ polyurethanes,⁶⁹ vinyl alcohol copolymers,⁷⁰ and thermal decomposition and branching reactions of aromatic esters.⁷¹

In view of current interest in ceramics, a number of papers have appeared describing the use of NMR to study polymeric precursors and the pyrolytic processes leading to the formation of ceramics. For example, the pyrolyses of polysilazane (precursor to silicon nitride),^{72,73} and of polycarbosilane and polysilane (precursor to silicon carbide)⁷² have been studied using solid state NMR techniques.

8 CURING REACTIONS

For thermosetting polymers, the curing reactions are a key step to achieve their end-use properties. In the early stages of curing when the reaction mixture is a liquid, the reaction can often be studied by liquid state NMR. Beyond the gel point, solid state NMR techniques have to be used.

A fair number of publications have appeared on thermosetting polymer systems. Some examples include phenol/formaldehyde resins,^{74–77} furfuryl alcohol resins,⁷⁹ cyanate polymers,⁸⁰ urea–formaldehyde resins,⁷⁸ acetylene-terminated polyimides,⁸² and polymers containing maleimide.^{83,84}

9 ESTER AND AMIDE INTERCHANGE REACTIONS

Blends of condensation polymers may undergo interchange reactions that may promote polyblend phase homogeneity.^{85,86} An example of polyamide/polyamide interchange is that with poly(*m*-xylene adipamide) and Nylon-6.⁸⁷ Examples of polyester/polyester interchange include those of polyarylate/poly(butylene terephthalate),⁸⁸ polycarbonate/poly(butylene terephthalate),⁸⁹ and polycarbonate/poly(ethylene terephthalate).⁹⁰

1 INTRODUCTION

Synthetic polymers can be made from monomers through either addition or condensation polymerization.¹ Condensation (or step-growth) polymers are made from monomers through condensation or related reactions, frequently involving the loss of a small molecule. An example is the production of Nylon-6,6, which is a polyamide:

Other condensation polymers include polyesters, polyurethanes, polysiloxanes, polysulfides, cellulosic derivatives, and phenol-formaldehyde, urea-formaldehyde and melamine-formaldehyde resins.

Addition (or chain-growth) polymers are those made from monomers without the loss of small molecules, the most common being vinyl and vinylidene polymers, i.e.,

where X and Y can be any substituents, e.g., hydrogen and halogen, alkyl and aryl, carboxyl and carbonyl, alcohol and ether. Polymerization may be accomplished through a reaction mechanism involving free radical, cationic, anionic, or metal complexes. Other common addition polymers are made from dienes, acetylenes, and aldehydes. A related category comprises polymers made from ring-opening polymerization, e.g., the polyethers:

In polymer studies, NMR has been extensively used to identify major or minor components in polymers, to determine polymer stereochemistry (tacticity), copolymer sequence structures, and substitution patterns in cellulosic derivatives, to identify and quantify chain branching, defect structures, and

Figure 1 Statistical models of polymerization

chain ends, and to study polymerization reaction mechanisms. The literature is rather voluminous, and has been reviewed previously.²⁻⁴

In NMR studies of polymer microstructure and polymerization mechanisms, statistical probability models have been found to be a convenient theoretical framework for analysis. Over the years, many statistical models have been devised, and are now used routinely. Associated with these models are a number of analytical methodologies that have been developed to treat NMR data. For convenience, these models are shown schematically in Figure 1.

2 ONE STATE MODELS

In most applications of NMR to polymers, the one-component statistical model is used. The polymer is assumed to form homogeneously via one reaction mechanism that can be described by one statistical model. Two types of structural features are commonly observed: stereochemistry (tacticity) of homopolymers and sequence placements of copolymers. A third type (regioirregular structures) can also occur, but is less frequently studied.

2.1 Copolymer Sequence

The simplest model is based on Bernoullian (B) statistics, where the addition of a monomer to a growing polymer chain does not depend on the identity of the monomer on the chain, but only on the instantaneous concentrations of the comonomers present. Thus, for a copolymer derived from comonomers M_1 and M_2 , the propagation equations are

where $(-)$ represents the polymer chain, $*$ represents a free radical, a cation, an anion, or a metal in a catalytic complex, and k_1 and k_2 are the rate constants of the comonomer addition reaction. The reactivity ratio r can be defined as

k_1/k_2 . The conditional probabilities for M_1 and M_2 (P_1 and P_2 , respectively) are

$$P_1 = \frac{rx}{1+rx}, \quad P_2 = \frac{1}{1+rx} \quad (6)$$

where $x = (M_1)/(M_2)$, with (M_1) and (M_2) the feed concentrations of M_1 and M_2 .

A slightly more complex model occurs when the addition depends not only on x but also on the reactivity of the last unit on the growing polymer chain. This is the first-order Markovian (**M1**), or terminal, statistical model:

The conditional probabilities are

$$P_{12} = \frac{1}{1+r_1x}, \quad P_{21} = \frac{1}{1+r_2/x} \quad (11)$$

where P_{ij} is the probability of comonomer j adding to a propagating chain terminating in monomer residue i , and the reactivity ratios $r_1 = k_{11}/k_{12}$ and $r_2 = k_{22}/k_{21}$. Reaction probability expressions for the various n -ad sequences can

be derived for the Bernoullian and first-order Markovian models.³⁻⁵ These are given in Table 1.

In the second-order Markovian (**M2**), or penultimate, statistical model, the probability of monomer addition depends on the identity of the last *two* units of the propagating chain. Four conditional probabilities are needed: $\alpha = P_{111}$, $\beta = P_{121}$, $\gamma = P_{211}$, and $\delta = P_{221}$, where P_{ijk} is the probability of comonomer k adding to a propagating chain terminating in residues i and j . For completeness, the reaction probability expressions³⁻⁵ for this model are also given in Table 1.

For example, the two-dimensional $^{13}\text{C}/^1\text{H}$ shift-correlated plot⁶ for a copolymer of ethylene (E) and vinyl chloride (V) is given in Figure 2. The spectral assignments are given in Table 2, where the nomenclature shown for (1)–(4) is used.⁷

The comonomer sequence distribution can be derived from the spectral intensities of either the ^1H or the ^{13}C NMR spectrum.^{6,8-10} The sample shown in Figure 2 has the

^aFor tacticity, the substitution ($A \rightarrow m$, and $B \rightarrow r$) should be made in the expressions for the **B**, **M1** and **M2** models.

^b $\alpha = P_{aaa}$, $\beta = P_{aba}$, $\gamma = P_{baa}$, $\delta = P_{bba}$.

^c $t = P_1(1 - P_1)$.

Figure 2 Two-dimensional ^{13}C - ^1H shift-correlation plot for ethylene-vinyl chloride copolymer, obtained at 300 MHz (^1H) and 75 MHz (^{13}C).⁶ The shift reference is hexamethyldisiloxane (HMDS). The numbering conforms to Table 2. Reproduced by permission of the American Chemical Society

composition E : V = 0.43 : 0.57. It turns out that this copolymer conforms well to a first-order Markovian model. The observed and calculated ^1H intensities are given in Table 2. The product $r_1 r_2$ of the reactivity ratios is 1.4.

An example of a condensation polymer can be given for the copolymer of dimethylsiloxane (M) and diphenylsiloxane (P). The ^{29}Si spectra of two copolymers prepared through ring-opening polymerization of methyl tetramer and phenyl

Figure 3 ^{29}Si NMR spectra of poly(dimethylsiloxane-co-diphenylsiloxane), obtained at 79.5 MHz: (a) sample 3; (b) sample 1.¹¹ Reproduced by permission of the American Chemical Society

tetramer are given¹¹ in Figure 3. The high-frequency (down-field) resonances (at approx. -20 ppm) are due to (SiMe_2O) , and the low-frequency resonances (at approx. -47 ppm) are due to (SiPh_2O) . In both regions, the ^{29}Si resonances are sensitive to pentads¹²⁻¹⁴ (Table 3). The polymerization reaction in this case is random; the spectral intensities conform to the Bernoullian model. The calculated versus the observed intensities are also shown in Table 3.

Thus far, only copolymers containing two comonomers have been considered. In three-component copolymerization, three comonomers are polymerized, and the first-order Markovian model has been derived^{7,15} and used for the analysis of the ^{13}C NMR data of ethylene/propylene rubber⁷ and ethylene/vinyl alcohol copolymers.¹⁵

Occasionally, four-component copolymerization is needed. The first-order Markovian model for this copolymerization is more complex,¹⁶ and has been formulated in a convenient form for NMR applications.^{17a} The model has been successfully applied to ^{13}C NMR data on styrene/butadiene rubber.^{17b} More recently, the same model has been modified to be used in a general way for the treatment of the NMR data of regio-irregular polymers.¹⁸

Three other statistical models should be mentioned: the Markovian model with reversible propagation, the complex participation model, and the bootstrap model. These models are useful in specific cases. For example, some monomers have low ceiling temperatures such that propagation and depropagation can occur during polymerization. Polymerizations involving methyl methacrylate, α -methylstyrene, and sulfur dioxide may exhibit this effect. In such cases, the Markovian model

must be modified to account for depropagation.¹⁹ The treatment has been generalized to equilibrium copolymerizations.²⁰

In some copolymerizations, two comonomers may form a complex. Upon copolymerization, the two comonomers would then have a greater tendency to alternate. The complex participation model takes this complexation into account.^{21,22} This model is useful, for example, for copolymers involving maleic anhydride, which has a tendency to complex with many comonomers.

In the bootstrap model,^{23a} the comonomer concentration at the polymerization center is different from that in the bulk. It has been suggested for styrene/methyl methacrylate copolymerization that the comonomer concentration ratio at the polymerization center is related to the bulk concentration ratio through an equilibrium constant *K*, which then describes the bootstrap effect. The bootstrap model has now found additional experimental verification.^{23b}

2.2 Homopolymer Tacticity

In vinyl homopolymers, the configuration of the substituents *X* gives rise to tacticity [structures (5)–(7)]:

Two terminologies can be used for tacticity. In absolute configuration terms, the heterotactic sequence above can be represented as (11 $\bar{1}$), where 1 represents the *up* configuration, and $\bar{1}$ denotes the *down* configuration. Alternatively, one can consider the relative configuration of pairwise adjacent substituents; the heterotactic sequence is then (mr). Statistical models can be carried out using either terminology. In the absolute configuration (Price formalism),²⁴ one considers the polymer as a copolymer of two ‘comonomers’ (1) and ($\bar{1}$). In the relative configuration scheme (Bovey formalism),³ the polymer is regarded as a copolymer of two ‘comonomers’ (m) and (r).

Note that in NMR measurements, only the relative configuration is actually observed; thus, the Bovey formalism is more commonly used. The Price configuration is useful in Ziegler–Natta polymerization, where most catalysts are stereospecific. The statistical models (Bernoullian and Markovian) hold for both formalisms, although they take on different meanings.⁵ In the Bovey formalism (8), the first-order Markovian model means that the tacticity of the incoming monomer *j* depends on the previous tacticity (between units *i* and *i* – 1 on the propagating chain). In the Price formalism (9), this means that the configuration of unit *j* depends on the configurations of *two* previous units (*i* and *i* – 1). This represents the second-order Markovian model (in the Price formalism).

The reaction probability in both formalisms can be derived just as in the case of the copolymers. In the conventional first-order Markovian model (i.e., the Bovey formalism), the first-order Markovian probabilities are P_{mr} and P_{rm} . In the

Figure 4 Relationships between the Bernoullian (**B**), first-order Markov (**M1**), and second-order Markov (**M2**) models in the Bovey and the Price formalisms

Price formalism, four second-order Markovian probabilities are needed: $\alpha = P_{111}$, $\beta = P_{1\bar{1}1}$, $\gamma = P_{\bar{1}11}$, and $\delta = P_{\bar{1}\bar{1}1}$. For convenience, $\bar{\alpha} = 1 - \alpha$, $\bar{\beta} = 1 - \beta$, etc. The tacticity expressions are

$$\text{Bovey } (m) = k P_{rm} \quad (12)$$

$$(r) = k P_{mr} \quad (13)$$

$$\text{Price } (m) = (11) + (\bar{1}\bar{1}) = k'(\gamma\delta + \bar{\alpha}\bar{\beta}) \quad (14)$$

$$(r) = (1\bar{1}) + (\bar{1}1) = k'(2\bar{\alpha}\delta) \quad (15)$$

where $k = (P_{mr} + P_{rm})^{-1}$ and $k' = (\bar{\alpha}\bar{\beta} + 2\bar{\alpha}\delta + \gamma\delta)^{-1}$.

An analogous situation occurs in Bovey's Bernoullian model, which corresponds to the first-order Markovian model in the Price formalism. The relationship between the two formalisms has been reviewed,⁵ and is summarized in Figure 4.

The special case of the Price Bernoullian model needs to be considered; this model has no equivalence in the Bovey formalism. The catalytic site will have a reaction probability P_1 for the 1-configuration and $P_{\bar{1}}$ (or $1 - P_1$) for the $\bar{1}$ -configuration. The various n -ad sequences are as follows:

$$(m) = (11) + (\bar{1}\bar{1}) = P_1^2 + (1 - P_1)^2 \quad (16)$$

$$(r) = (1\bar{1}) + (\bar{1}1) = 2P_1(1 - P_1) \quad (17)$$

$$(mm) = (111) + (\bar{1}\bar{1}\bar{1}) = P_1^3 + (1 - P_1)^3 \quad (18)$$

$$\begin{aligned} (mr) &= (1\bar{1}\bar{1}) + (\bar{1}\bar{1}1) + (\bar{1}11) + (11\bar{1}) \\ &= 2P_1(1 - P_1)^2 + 2P_1^2(1 - P_1) \end{aligned} \quad (19)$$

$$(rr) = (1\bar{1}1) + (\bar{1}1\bar{1}) = P_1(1 - P_1)^2 + P_1^2(1 - P_1) \quad (20)$$

The Price Bernoullian model is also known as the symmetrical enantiomorphic-site (**E**) model,^{25–28} and is found to be suitable for stereospecific Ziegler–Natta polymers, where the polymerization is determined by catalytic sites only.

In general, the Bovey formalism is used for polymerizations which are controlled by the propagating chain ends; this is the most frequently encountered case. For polymerizations catalyzed by metal complexes (e.g., Ziegler–Natta catalysts), the catalytic site may dominate the reaction probability, and the Price formalism may be appropriate. The various mechanisms of stereochemical control and the suitable models can be summarized as follows:^{5,29}

1. pure chain-end control: Bovey **B**, **M1** and **M2** models;
2. pure catalyst-site control: **E** model (Price **B** model);
3. both catalyst-site and chain-end control: Price **M1** and **M2** models.

Figure 5 ^{13}C NMR spectrum of the methyl region (obtained at 90 MHz) for a sample of polypropylene made with $\text{Et}(\text{Ind})_2\text{ZrCl}_2$ (shown on the left) at 50°C

As an example, the ^{13}C NMR spectrum of the methyl substituent of polypropylene, prepared with a Zr metallocene/methyl aluminoxane,³⁰ is shown in Figure 5. The assignments³¹ are shown with the spectrum. The resonances are sensitive to the pentad level. For this sample,³⁰ the tacticity agrees with the E model with $P_1 = 0.92$.

2.3 Regioirregular Structures

In some polymers, head-to-head (**11**) and tail-to-tail (**12**) structures are found together with the normal, head-to-tail structure (**10**):

For a more detailed discussion of these regioirregular structures, see *Polymers: Regio-Irregular Structure*. The statistical models used for regioirregular structures have been reviewed in a recent article.¹⁸

3 TWO STATE MODELS

For convenience, one can distinguish two types of two state models.³² In *concurrent two state models*, two separate polymer components are present, which may be a result of deliberate polymer blending, programmed comonomer feed concentrations, or phase separation. Another possibility is

when two separate polymerization centers (or catalytic sites) are present, each center making its own polymer according to its propagation statistics. This is sometimes the case with some emulsion and Ziegler–Natta polymerizations.

In *consecutive two state models*, two polymerization centers are present, but they switch back and forth even as polymerization proceeds. As a result, one gets a block copolymer consisting of blocks that conform to different statistical models. Another case where this model holds is when sudden fluctuations in the reaction conditions occur during polymerization (e.g., changes in temperature, pressure, or comonomer concentrations). The polymer made during the change may also conform to the consecutive model.

The classic work on two state models is that of Coleman and Fox.³³ Their theory assumes two Bernoullian states (i.e., two state **B/B**), and includes both consecutive and concurrent cases. Its application to NMR data has been described by Frisch et al.,³⁴ especially in relation to the anionic polymerization of methyl methacrylate. An alternative two state model for anionic polymerization has been proposed by Khan and Hogan-Esch.³⁵ A generalized treatment of two state consecutive models has been devised³² using a structural approach. The general model can be used for consecutive two state **B/B**, **B/E**, and **E/E** cases. These models have been tested on anionic PMMA data and also on the tacticity data of polypropylene produced by nonsymmetric *ansa*-titanocene catalysts.³²

Concurrent two state models have been used for Ziegler–Natta polymers. Zambelli et al.³⁶ and Chujo et al.³⁷ first used the concurrent **E/B** model for the treatment of polypropylene tacticity, and the concurrent **B/B** model has been applied to olefin copolymers by Ross³⁸ and others.^{39–41} The mode of application of these concurrent two state models to the analysis of NMR data is similar to that of concurrent multistate models (see Section 4).

As a result of intensive research activities on homogeneous Group IV metallocene catalysts, a number of new two state models have been proposed. To rationalize the NMR data of syndiotactic polypropylene made with metallocene catalysts, Ewen et al.⁴² proposed a two state model based on dual catalytic-site and chain-end control. Cheng and Kasehagen^{43a}

have devised a two state model, attempting to explain the NMR tacticity data of polypropylene in general. Several other models have also been proposed.^{43b–d}

4 MULTISTATE MODELS

In many polymers of commercial interest, more than one or two components may be present. For example, heterogeneous Ziegler–Natta catalysts are known to contain at least three active sites.^{44,45} The NMR data for a polymer made with such a catalyst would have contributions from all the multiple components. A general methodology for the treatment of the NMR data of these polymers has been devised.⁴¹ Whereas the methodology can be used on the NMR data of the polymer as is, it has been found that best results are obtained when the NMR data of a *series* of polymer samples are available; for example, in the following cases.

1. The polymer is fractionated by a suitable means.^{41,46–51}
2. During polymerization, the polymerization reaction mixture is sampled at various conversions.
3. For copolymers, different copolymer compositions are made under similar reaction conditions, but with different feed comonomer concentrations.⁵²
4. A related series of polymers is obtained, prepared with essentially the same reaction conditions except that one experimental variable has been systematically varied.⁵³ That experimental variable should change the proportions of the components making up the polymer, but does not significantly change the polymer microstructure (e.g., stereospecificity, regiospecificity, and reactivity ratios).

In all four cases, the NMR data for the series of polymer samples or fractions are obtained and analyzed in a systematic manner. The methodology has been applied to copolymer sequence analysis of ethylene/propylene copolymer,^{41,46,47,52,53} propylene/1-butene copolymer,⁴¹ ethylene/1-butene copolymer,^{48,54} ethylene/1-hexene copolymer,^{52,55} and ethylene oxide/epichlorohydrin copolymer,⁵⁰ and to the tacticity determination of polypropylene,^{41,49,53} poly(1-butene),^{41,46} and polyepichlorohydrin.⁵¹

^aObserved data taken from T. Tsutsui, N. Ishimaru, A. Mizuno, A. Toyota, and N. Kashiwa, *Polymer*, 1989, **30**, 1351.

^bC5 = pentane, C6 = hexane, C7 = heptane, T = toluene.

An example is given for the NMR data of polypropylene made with a heterogeneous Ziegler–Natta catalyst.⁴⁹ The polymer has been fractionated and the NMR pentad intensities for the methyl resonances obtained (Table 4).

The data have been treated using the computerized analytical approach.⁴⁹ First, the pentad data for each fraction are analyzed using the one state and two state models. If there is strong evidence that the polymer contains multiple components then the pentad data from pairwise fractions are taken and simultaneously analyzed using the two state and the three state models. The results are compiled and checked for trends. Additional information (e.g., M_n and M_w) is included in the analysis. If the precision in the data is good, a decision can often be made as to the minimum number of states that the data need in order to obtain satisfactory goodness-of-fit. Finally, a global data fit can be carried out including the data of all the fractions. The result of this analysis for the polymer example is shown in Table 4. The polymer consists of at least four distinct components; three of them conform to the **E** model and one to the **B** model. Thus, the catalyst contains at least four active sites. Through further calculation,⁴⁹ it can be shown that the sites contribute 24.8%, 20.0%, 39.9%, and 15.3%, respectively, to polymer yield.

5 PERTURBED MODELS

As with molecular weights, most polymers do not have a single uniform composition; instead, a distribution of composition is obtained. This compositional heterogeneity can come about through many means,^{56,57} for example,

1. copolymer sequence
 - (a) statistical,
 - (b) conversion,
 - (c) multistate,
 - (d) process;
2. homopolymer tacticity
 - (a) statistical,
 - (b) chain end,
 - (c) multistate,
 - (d) process.

Statistical heterogeneity occurs as a result of different statistical combinations of the comonomers in a given polymer chain. Conversion heterogeneity is found in copolymers when two comonomers have different reactivities; thus, at low conversions, the polymer chains produced are enriched in the more reactive comonomers, and at high conversions, the polymer contains the comonomers that are left over. Multistate heterogeneity has been described in the previous section. Process heterogeneity is a result of fluctuations in the polymerization processes. These various heterogeneities separately or together have an effect on the copolymer sequence or tacticity. Perturbed Markovian⁵⁸ and enantiomorphic-site⁵⁹ models have been developed. Similar equations for the Bernoullian model were derived earlier by Ross.³⁸ Using the perturbed model, one can analyze⁵⁸ or simulate^{56,57} the NMR data and the compositional distribution curves.

The perturbation model is particularly useful⁶⁰ when the polymer molecular weights are low, or when there are large fluctuations in the reaction conditions during polymerization. Another pertinent situation occurs in copolymerization when the reactivity of the comonomers involves uncertainty (e.g.,

with the active catalytic site exhibiting a distribution of selectivities). The resulting reaction probability would then have a range of values: $P_{ij} = \langle P_{ij} \rangle \pm \epsilon$, where P_{ij} and $\langle P_{ij} \rangle$ are the actual and average reaction probabilities, respectively, and ϵ is a measure of the distribution. A similar situation may arise if the tacticity control of the active site is partial or imprecise.

6 ANALYTICAL METHODOLOGIES

In order to apply these various models to actual data, appropriate analytical methodologies are needed. In the *analytical* (model-fitting) approach,^{14,15,41,49,52,53,61,62} the observed NMR spectrum is interpreted and the spectral intensities fitted to a reaction probability model:

$$\begin{array}{ccccccc} \text{observed} & & \text{spectral} & & \text{fitting} & & \text{probability} \\ \text{data} & \longrightarrow & \text{interpretation} & \longrightarrow & \text{algorithm} & \longrightarrow & \text{model} \end{array} \quad (21)$$

This approach has been used for the analyses of the data in the preceding sections. The analyses can be facilitated with the use of computers.

In the *synthetic* (or computer simulation) approach,^{29,56,57,61,63,64} one starts with the statistical model and carries out ‘model calculations’ to derive the predicted NMR information:

$$\begin{array}{ccccccc} \text{probability} & & \text{model} & & \text{bookkeeping} & & \text{predicted} \\ \text{model} & \longrightarrow & \text{calculations} & \longrightarrow & \text{procedures} & \longrightarrow & \text{results} \end{array} \quad (22)$$

The ‘model calculations’ may involve theoretical derivations of reaction probabilities, or Monte Carlo simulation of polymerization to generate an ensemble of polymer chains. In the latter case, one then needs to count the polymer chains and sort them according to the information needed. In this way, polymer sequence, composition distribution, molecular weights, and even simulated NMR spectra can be obtained.

The relative merits of these two approaches have been discussed in the literature.⁶¹ In general, they are complementary; the use of both can provide a rather detailed understanding of the polymer in question.

1 INTRODUCTION

'Regio-irregular structure' generally refers to the structure of regio-irregular polymers prepared with unsymmetrically substituted vinyl monomers ($\text{CHR}=\text{CH}_2$). The orientational mode adopted by such an asymmetric monomer on entering the growing chain leads normally to a regular chemical arrangement of the monomer units, i.e., head-to-tail (H-T) (1), in addition polymerization reactions.

In contrast, the alternative head-to-head (H-H) and the accompanying tail-to-tail (T-T) structures (2) are not favored, although some of these sequences may be found in some polymers. In a few cases the proportion of (H-H) and (T-T) structures can be relatively high; it can reach 30–40% in polypropylene (PP),¹ poly(1-butene)² and poly(vinyl fluoride), but about 5% is a more usual level.^{3,4}

The presence of such arrangements must be taken into account while interpreting the ^{13}C or ^{19}F NMR spectra of these polymers, because this probe is very sensitive both to chemical and steric structure, and, from a detailed knowledge of the structure, information can be drawn on the polymerization mechanism.⁴

As the proportion of the regio-irregular structure in the sample increases, peak assignment becomes very complex because of the coexistence of several kinds of sequence containing inverted units and also the fine splitting of each peak due to stereoregularity. Several NMR techniques including sample preparation have been used for peak assignment: 2D INADEQUATE,^{1,2} INEPT and DEPT,^{1,2,5} ^{13}C - γ shielding calculations with a rotational isomeric state (ris) model,^{5,6} empirical chemical shift rules,⁷ and the

preparation of several ^{13}C -enriched model compounds for irregularly arranged sequences in the polymers.⁸ Since the ^{13}C NMR assignment of regio-irregular PP has been reported most frequently, the assignment will be described here in detail. Then the NMR analysis of other regio-irregular polymers will be reviewed.

2 ^{13}C NMR SPECTRUM OF REGIO-IRREGULAR POLYPROPYLENE

Figure 1 shows the ^{13}C NMR spectrum of regio-irregular PP containing up to 40 mol% of inverted propylene units along with the stick spectra calculated according to the Lindeman–Adams empirical rules.^{9,10} Here, the letters S, T and P are used when we refer to secondary (CH_2), tertiary (CH), and primary (CH_3) carbons, respectively. Two Greek subscripts are used, referring to the distances of the nearest methyl groups from the carbon in question. Four Greek subscripts are used when referring to the distances of the two nearest methyl substituents on each side of the given carbon.^{11–13} The sample giving rise to Figure 1 is atactic, judging from the peak patterns of the carbons, $\text{P}_{\beta\beta}$ and $\text{S}_{\gamma\alpha\gamma}$.¹⁴ For the empirical chemical shift calculation, the presence of five kinds of sequence containing H-H and/or T-T units in the sample is assumed as follows:

- the sequence (3) where an isolated H-H unit is involved,

- the sequence (4) where an isolated T-T unit is involved,

- the sequence 1-r (5), where a single inverted unit in the successive H-T units is involved,

Figure 1 100 MHz ^{13}C NMR spectrum of regio-irregular polypropylene containing many inverted propylene units [sample concentration 12% (w/v), 15 254 pulses]. The stick spectra were calculated using the Lindeman–Adams chemical shift empirical rules by assuming the presence of several kinds of sequence in the chain

4. the sequence 2U-r (6), where two successive inverted units in the H-T units are involved,

5. the sequence 2-r (7), where an inversion occurs, followed by a second inversion,

It is possible to speculate on the presence of several kinds of sequences from a comparison of the calculated and observed chemical shifts, although the agreement is extremely poor in the methylene carbon region. Consequently, it is difficult to assign these peaks to the individual carbons of the sequences assumed.

The ^{13}C NMR spectral assignment is not easy because of overlapping of the peaks, especially in the region from 30 to 40 ppm. One of the reasons for the complexity of this spectral region is overlapping of the CH and CH_2 peaks. Therefore, assignment of these peaks to the CH and CH_2 carbons is performed using the INEPT technique,¹⁵ as shown in Figure 2.

The INEPT ($\Delta = 2/4J^*$) observation gives only the CH spectrum (b). Then, only the CH_2 spectrum (c) is obtained from the difference between the ^1H -decoupled (a) and INEPT ($\Delta = 2/4J^*$) (b) spectra. Here the peak of the CH carbon from the successive H-T units, $\text{T}_{\beta\beta}$, was used as a reference. From these spectra, it is observed that all peaks between 36.5 and 39 ppm are clearly assigned to CH carbons, and the peaks at 32.6 and 33.4 ppm to the CH_2 carbons. The CH and CH_2 peaks overlap in the spectral region 34–36.5 ppm, and are identified for each carbon by the INEPT technique. In addition, small CH_2 peaks overlapping with the CH peak at 31 ppm are detected in the difference spectrum. Thus, all of the peaks are classified into the CH, CH_2 , and CH_3 carbons.

3 2D INADEQUATE SPECTRUM OF REGIO-IRREGULAR POLYPROPYLENE

A 2D INADEQUATE experiment, which makes it possible to assign carbons to specified sequences through the ^{13}C – ^{13}C connectivities, is then performed.¹⁶

Figure 2 100 MHz ^{13}C NMR spectra of regio-irregular polypropylene (the spectral region 29.9–40 ppm is expanded): (a) ^1H completely decoupled; (b) INEPT ($\Delta = 2/4J^*$, 17 497 pulses) CH only; (c) difference, (a) – (b), CH_2 -only. The CH peak $\text{T}_{\beta\beta}$ carbon in head-to-tail units was used as a reference to obtain the difference spectrum (c)

Figure 3 shows the 2D INADEQUATE spectrum of regio-irregular PP. The ^{13}C – ^{13}C connectivities of the carbons in the isolated H-H and T-T units are shown as solid and broken lines, respectively. Assignment of the peaks attributable to the carbons in these units is relatively easy. The assignments due to stereoregularity are also possible at the diad level. In the

Figure 3 100 MHz 2D INADEQUATE ^{13}C NMR spectrum of regio-irregular polypropylene. The ^{13}C – ^{13}C connectivities of the carbons in the isolated head-to-head and tail-to-tail units are shown as solid and broken lines, respectively

Figure 4 100 MHz 2D INADEQUATE ^{13}C NMR spectrum of regio-irregular polypropylene. The ^{13}C – ^{13}C connectivity of the carbons in the sequence 1-r, where there is a single inverted unit in the successive head-to-tail units, is shown as a solid line

region 14–18 ppm, the lower-frequency (higher field) peak at 14.7–15.1 ppm has already been assigned to be the carbon $\text{r}_0\text{-P}_{\alpha\beta}$, and the higher-frequency peak at 16.6–17.2 ppm is assigned to $\text{m}_0\text{-P}_{\alpha\beta}$ in the H-H unit of PP. Therefore, in the CH spectrum of Figure 2(b), the spectral region 34.2–35.6 ppm is assigned to the carbon $\text{T}_{\alpha\beta}(5)$ in the H-H units from the ^{13}C – ^{13}C connectivities (solid lines). The number in parentheses refers to the carbon in the structure in Figure 1. The peaks between 34.2 and 34.8 ppm are assigned to the $\text{r}_0\text{-T}_{\alpha\beta}$ carbons, and the peaks between 35.4 and 35.6 ppm to the $\text{m}_0\text{-T}_{\alpha\beta}$ carbon. Similarly, in the region 40–45 ppm, the peaks at 40.9–42.3 ppm are assigned to $\text{m}_0\text{-S}_{\beta\alpha\alpha\gamma}$, and the higher-frequency peaks at 43.3–44.1 ppm to $\text{r}_0\text{-S}_{\beta\alpha\alpha\gamma}$. Further splittings of these peaks are due to both the stereoregularity and the presence of other carbons in the sequences, except for the isolated H-H and T-T units. The assignments of the peaks of the carbons in the T-T unit are also performed by the 2D INADEQUATE method.

Table 1 ^{13}C NMR Chemical Shifts of the Carbon $\text{S}_{\gamma\alpha\beta\gamma}$ [see (8)] in the Sequence 1-r Calculated at the Pentad Level on the Basis of the ^{13}C NMR γ -Effect and Ris Model, (a) and with the Empirical Additivity Rules Proposed by Cheng and Bennett (b)

	$\begin{matrix} \text{m}_1 & \text{m}_1 & \text{m}_2 & \text{m}_0 \\ \text{r}_1 & \text{r}_1 & \text{r}_2 & \text{r}_0 \end{matrix}$	
	$\begin{matrix} \text{C} & \text{C} & \text{C} & \text{C} \\ & & & \\ \text{C}-\text{C}-\text{C}-\text{C}-\text{C}-\text{C}-\text{C}-\text{C} \end{matrix}$	
Sequence	(a) ^a	(b) ^a
$\text{m}_1\text{m}_1\text{m}_2\text{r}_0$	0.00	0.00
$\text{m}_1\text{m}_1\text{r}_2\text{r}_0$	−0.09	−0.08
$\text{m}_1\text{r}_1\text{r}_2\text{r}_0$	0.86	1.07
$\text{m}_1\text{r}_1\text{m}_2\text{r}_0$	0.92	1.18
$\text{r}_1\text{r}_1\text{m}_2\text{r}_0$	0.75	1.04
$\text{r}_1\text{r}_1\text{r}_2\text{r}_0$	0.68	0.92
$\text{r}_1\text{m}_1\text{r}_2\text{r}_0$	0.13	0.08
$\text{r}_1\text{m}_1\text{m}_2\text{r}_0$	0.22	0.16

^aIn ppm from $\text{m}_1\text{m}_1\text{m}_2\text{r}_0$ (assumed to be 0 ppm).

The appearance of the peak at 32.6 ppm, assigned to the $S_{\delta\beta\alpha\beta}$ (14) carbon, indicates the presence of the sequence 1-r (see Figure 1). This is supported by the ^{13}C – ^{13}C connectivities of the 2D INADEQUATE spectrum (solid line in Figure 4).

Grassi et al.¹⁷ have reported the ^{13}C NMR spectrum of *isotactic* regio-irregular PP containing exclusively the sequence 1-r in successive H-T units. Their data constitute a reference for the chemical shifts of the isotactic peaks of the sequence 1-r. By comparison, the absence of the m_0 – $S_{\delta\beta\alpha\beta}$ peak in this spectrum is clearly indicated because there are no peaks around 30.4 ppm. Thus, there is a ^{13}C – ^{13}C connectivity between r_0 – $P_{\alpha\beta}$ and r_0 – $S_{\beta\alpha\alpha\gamma}$ but no connectivity between the m_0 – $P_{\alpha\beta}$ and r_0 – $S_{\beta\alpha\alpha\gamma}$ peaks.

Nine kinds of carbons, 11–19 in the sequence 1-r, can be assigned through ^{13}C – ^{13}C connectivities (Figure 4). The peaks of three kinds of CH carbons, namely, $T_{\delta\beta\gamma\delta}$ (11), $T_{\delta\gamma\alpha\gamma}$ (15), and $T_{\delta\alpha\beta\delta}$ (17), were observed. The peak position of the $T_{\delta\beta\gamma\delta}$ carbon in the sequence 1-r coincides with that of the $T_{\delta\beta\gamma\delta}$ carbon in the isolated T-T unit. In addition, the peak of the r_0 – $T_{\delta\alpha\beta\delta}$ carbon, which was separated from the CH_2 peaks by the INEPT technique (Figure 2), appears at 34.5 ppm, the same region as the peak of the carbon r_0 – $T_{\alpha\beta}$ in the H-H unit.

There are also three kinds of CH_2 carbons, namely, $S_{\gamma\alpha\beta\gamma}$ (13), $S_{\delta\beta\alpha\beta}$ (14), and $S_{\beta\alpha\alpha\gamma}$ (19), in the sequence 1-r. The peak at 32.6 ppm is assigned to the r_0 – $S_{\delta\beta\alpha\beta}$ carbon as mentioned above. In the resonance region, 34–36.7 ppm, three CH_2 peaks are observed (Figure 2). The lowest-frequency peak has already been assigned to the m_1 – $S_{\gamma\alpha\beta\delta}$ carbon, and the center peak to the r_1 – $S_{\gamma\alpha\beta\delta}$ carbon. The ^{13}C NMR chemical shifts of the $S_{\gamma\alpha\beta\gamma}$ carbon in the sequence 1-r are calculated on the basis of the γ -shielding effect and the ris model.^{5,6,18} The chemical shifts of the same carbon are also calculated with the empirical rules reported by Cheng and Bennett.⁷ The results are listed in Table 1. Both calculated results indicate that the peak of the r_1 – $S_{\gamma\alpha\beta\gamma}$ carbon should appear at higher frequency by approx. 0.6–1 ppm from the peak of the m_1 – $S_{\gamma\alpha\beta\gamma}$ carbon, where m_1 and r_1 imply the stereoregularity indicated by the arrow in Table 1. Thus, the CH_2 peak at 36.5 ppm is assigned to the r_1 – $S_{\gamma\alpha\beta\gamma}$ (13) carbon in the sequence 1-r. The peak at 35.5 ppm, which was already assigned to the r_1 – $S_{\gamma\alpha\beta\delta}$ carbon in the isolated T-T unit might contain the m_1 – $S_{\gamma\alpha\beta\gamma}$ carbon in the sequence 1-r. The peak of the r_0 – $S_{\beta\alpha\alpha\gamma}$ (19) carbon is observed at 43–44 ppm, where the peak of the r_0 – $S_{\gamma\alpha\alpha\beta}$ carbon in the H-H unit also appears. The peaks of the CH_3

Table 2 ^{13}C NMR Chemical Shift Assignments of Regio-Irregular Polypropylene

^aTentative assignment.

carbons, $r_0\text{-P}_{\delta\gamma\alpha\gamma}(16)$ and $r_0\text{-P}_{\delta\alpha\beta\delta}(18)$ in the sequence 1-r coincide with the peak of the $r_0\text{-P}_{\alpha\beta}$ carbon in the isolated H-H unit. There remain other $^{13}\text{C}\text{-}^{13}\text{C}$ connectivities, and it is therefore necessary to consider the presence of other sequences in this regio-irregular PP.

Most of the peaks of the carbons in the sequence 2U-r occur where two successive inverted H-T units overlap with those in the isolated H-H and T-T units (Figure 1). However, the presence of the ^{13}C – ^{13}C connectivities among carbons-21, -23 and -24 in the 2D INADEQUATE spectrum indicates strongly the presence of the sequence 2U-r. This is a merit of the 2D INADEQUATE method, because it is difficult to detect a 2U-r sequence in the usual one-dimensional NMR spectrum.

The presence of the sequence 2-r where an inversion occurs, followed by a second inversion, is also considered for the following reasons.

1. The CH₂ peak at 33.4 ppm (Figure 2c) remains unassigned. If there is a sequence 2-r then the appearance of the peaks of carbons-31 and -32 is predicted to be at a slightly higher frequency than the peak of the r₀-S_{αβαβ} carbon (32.6 ppm) in the sequence 1-r (Figure 1).
2. The CH₂ peak at 31.2 ppm (Figure 2c) remains unassigned.
3. The peak intensity of the T_{αγ} carbon (36.8–39.1 ppm) in the sequence 1-r is too strong (Figure 2b). The discrepancy is reasonably interpreted with the appearance of the T_{αγ}(27), (29), and (33) peaks by assuming the presence of the sequence 2-r.
4. The presence of the sequence 2-r, as well as the other sequences, is confirmed in a regio-irregular poly(1-butene) sample containing many inverted butene units. The catalytic system of polymerization is similar to that used in the case of the regio-irregular PP considered here.

4 ¹³C NMR ASSIGNMENT OF REGIO-IRREGULAR POLYPROPYLENE

The chemical shifts and final assignments are summarized in Table 2. It should be emphasized here that detailed assignment of the carbon resonances of regio-irregular PP is performed using the 2D INADEQUATE technique, the INEPT technique, and ^{13}C chemical shift calculations. An analytical approach on the basis of the assigned peaks of regio-irregular PP has been developed using the reaction probability model by Cheng.⁴

5 OTHER REGIO-IRREGULAR POLYMERS

A similar approach has also been applied to the ^{13}C NMR assignment of regio-irregular poly(1-butene), PB.² Only the spectrum and the final assignments are shown in Figure 5, where the side-chain secondary and primary carbons are designated by s-S and P, respectively, and the main-chain secondary and tertiary carbons by m-S and T, respectively. The sequences containing H-H and/or T-T units in the regio-irregular PB sample are the same as those in the regio-irregular PP sample.

Poly(vinylidene fluoride) (PVF₂), $-(CF_2-CF_2)-$, as normally obtained by free radical polymerization, is not completely regio-regular, resulting in the creation of between 3.5 and 6% defects or regio-irregularities.¹⁹ Figure 6 presents the completely decoupled ¹³C NMR spectrum of PVF₂ obtained using the triple resonance technique to delete the usual multiplet pattern of ¹⁹F-coupled ¹³C resonances.

The ^{13}C chemical shift calculations have been performed on the basis of the β - and γ -shielding effects and the ris model for the sequence containing inverted monomer units as shown in Figure 6. The agreement between the calculated

Figure 5 67.8 MHz ^{13}C NMR spectrum of regio-irregular poly(1-butene), together with the assignments

Figure 6 22.5 MHz ^{13}C NMR spectra of poly(vinylidene fluoride). The stick spectra are calculated on the basis of the β - and γ -shielding effects and the ris model for the sequence containing inverted monomer units

(stick spectra) and observed chemical shifts is good, and the assignment is easily performed.²⁰ The ^{19}F NMR spectrum has also been observed, and the assignment is reported on the basis of similar chemical shift calculations.²¹

Regio-sequence defects in propylene oxide have been analyzed in detail by Tonelli and co-workers²² using ^{13}C NMR.

1 INTRODUCTION

This article is concerned with the application of high-resolution NMR relaxation techniques in studying the mechanisms and rates of motions of synthetic polymers in dilute solutions. Such measurements provide data on the physical state of dissolved polymers, on polymer-solvent interactions, and on the intramolecular factors which control chain dynamics.

Perhaps the first qualitative observation on this subject was made by Bovey et al.¹ in their pioneering work on the use of high-resolution NMR to determine the structure of polymers, where they found that high-resolution spectra were obtained from solutions of polymers of such high molecular weight that the rate of overall tumbling of the molecule as a whole would be far too slow to average dipole-dipole coupling. Their conclusion, that magnetic relaxation was in fact largely controlled by rapid small-scale segmental motions, has formed the basis of subsequent approaches to the interpretation of relaxation measurements of random coil polymers in dilute solution. Exceptions to this general principle are found in three situations: (i) when the polymer is capable of adopting a regular relatively rigid conformation, e.g. the helical conformation of synthetic polypeptides; (ii) when the polymer may associate into a colloidal structure, e.g. the micellar structure adopted by block copolymers in selective solvents; and (iii) solutions which are sufficiently concentrated that chain entanglements hinder the complete averaging of dipole-dipole coupling. This article first surveys the general features of relaxation of single chains in solution, then describes the theoretical approaches which have been developed to interpret relaxation times quantitatively in terms of chain motions. These topics have been covered in considerable detail previously in numerous books and reviews.²⁻⁷ A useful annual survey appears in the Nuclear Magnetic Resonance volume of the Specialist Periodical Reports published by the Royal Society of Chemistry, London, UK.

2 BASIC ASPECTS OF RELAXATION STUDIES OF POLYMERS

The vast majority of studies of the type under discussion here have used either ¹H or natural abundance ¹³C NMR. In polymers, the relaxation of protons and protonated saturated ¹³C nuclei is determined essentially by intramolecular dipole-dipole (DD) interactions with neighboring ¹H nuclei. The spin-rotation (SR) mechanism and relaxation by dissolved oxygen are usually insignificant, though the chemical shift anisotropy (CSA) mechanism is important for unsaturated ¹³C nuclei at magnetic fields above ca. 5 T. Carbon-13 NMR has two advantages which outweigh its greatly reduced sensitivity compared to ¹H NMR. First, the resolution of small structural differences in ¹³C spectra is better so that the motions of different chain fragments can be studied more closely. Second, relaxation of a protonated ¹³C nucleus is determined almost entirely by DD interaction with the attached proton(s). Since the C-H bond length may be estimated with reasonable accuracy, the precise determination of correlation times is thereby facilitated. In contrast, ¹H NMR spectra are frequently poorly resolved, while ¹H relaxation is controlled by DD interactions with numerous geminal, vicinal, or more distant neighbors whose separations depend on perhaps poorly characterized chain configuration and conformation.

The ultimate objective of dynamic studies is to determine the correlation function, $G(\tau)$, for some time-dependent function which depends on the relaxation mechanism (see *Brownian Motion and Correlation Times*). For DD relaxation, the functions are second-order harmonic functions of the Euler angles describing the orientation of internuclear vectors. NMR relaxation times depend on $G(\tau)$ indirectly through the spectral density function, $J(\omega)$, which is related to $G(\tau)$ via

$$J(\omega) = \int_{-\infty}^{+\infty} G(\tau) \exp(i\omega\tau) d\tau \quad (1)$$

In a given magnetic field, relaxation times depend on values of $J(\omega)$ at a limited number of frequencies. For relaxation of the ¹³C nucleus in a ¹³CH_n group by DD interaction with the attached protons under ¹H-decoupled conditions, $G(\tau)$ is the autocorrelation function for the C-H bond, and T_{1C} , T_{2C} , and the ¹³C-¹H nuclear Overhauser enhancement factor, η , are given by

$$\frac{1}{T_{1C}} = Q[J(\omega_H - \omega_C) + 3J(\omega_C) + 6J(\omega_H + \omega_C)] \quad (2)$$

$$\frac{1}{T_{2C}} = \frac{Q}{2}[4J(0) + J(\omega_H - \omega_C) + 3J(\omega_C) + 6J(\omega_H) + 6J(\omega_H + \omega_C)] \quad (3)$$

$$\eta = \left(\frac{\gamma_H}{\gamma_C}\right) \left[\frac{6J(\omega_H + \omega_C) - J(\omega_H - \omega_C)}{J(\omega_H - \omega_C) + 3J(\omega_C) + 6J(\omega_H + \omega_C)} \right] \quad (4)$$

where

$$Q = \frac{1}{20} \left(\frac{\mu_0}{4\pi}\right)^2 \frac{n\gamma_H^2\gamma_C^2 h^2}{4\pi^2 r_{CH}^6} \quad (5)$$

r_{CH} is the C-H bond length and other symbols have their standard meanings. [Note that in these equations, the functions

$J(\omega)$ are defined in terms of a normalized correlation function, i.e., $G(0) = 1$.]

For ^1H relaxation, except for a few very simple chains, there are usually several resolvable groups of protons. Longitudinal relaxation is governed by the set of coupled equations

$$\frac{dM_{zi}}{dt} = -\rho_i(M_{zi} - M_{zi}^0) - \sum_{j \neq i} \sigma_{ij}(M_{zj} - M_{zj}^0) \quad (6)$$

where M_{zi} is the longitudinal magnetization of spin i , the superscript 0 denotes equilibrium values, and the relaxation coefficients are given by

$$\rho_i = \sum_{j \neq i} C_{ij}[J(\omega_i - \omega_j) + 3J(\omega_i) + 6J(\omega_i + \omega_j)] \quad (7)$$

$$\sigma_{ij} = C_{ij}[6J(\omega_i + \omega_j) - J(\omega_i - \omega_j)] \quad (8)$$

$$C_{ij} = \frac{1}{20} \left(\frac{\mu_0}{4\pi} \right)^2 \frac{\gamma_H^4 h^2}{4\pi^2 r_{ij}^6} \quad (9)$$

(See *Relaxation Processes in Coupled-Spin Systems*). For nonselective pulses under extreme narrowing $[(\omega_i + \omega_j)^2 \tau_c^2 \ll 1]$, each spin relaxes at a characteristic rate with a time constant given approximately by

$$\frac{1}{T_{1i}} = \rho_i + \sum_{j \neq i} \sigma_{ij} \quad (10)$$

However for slow motion $[(\omega_i + \omega_j)^2 \tau_c^2 \gg 1]$, rapid cross relaxation (spin diffusion) arising from the $J(\omega_i - \omega_j)$ terms maintains a uniform spin temperature, and all spins relax at the same population-weighted average rate. The cross-relaxation rate σ_{ij} gives access to the spectral density at very low frequencies of the order of differences in ^1H resonance frequencies, and can be measured using selective perturbation methods.⁴ It also gives rise to ^1H - ^1H NOEs, much used in the study of the structure of biological macromolecules but only rarely applied to synthetic polymers. Recently NOEs have been used to study the conformation of polyesters⁸ and the miscibility of poly(methyl acrylate) and poly(vinyl acetate) in solution.⁹

Because NMR relaxation depends on the motion of a single bond or short range internuclear vector, relaxation measurements are in principle capable of giving detailed insight into the nature of the polymer motions at the functional group level.

For isotropic rotation, $G(\tau)$ is exponential:

$$G(\tau) = \exp(-|\tau|/\tau_c) \quad (11)$$

and $J(\omega)$ becomes

$$J(\omega) = \frac{2\tau_c}{1 + \omega^2 \tau_c^2} \quad (12)$$

where τ_c is the correlation time. However in a complex dynamic system such as a random coil in solution, it is not to be expected, nor do experimental data show, that $G(\tau)$ is such a simple function. In order to gain insight into the form of $G(\tau)$, and hence the motional mechanism,

it is necessary to measure several relaxation parameters at different resonance frequencies. For ^{13}C measurements, the relaxation data set normally comprises T_1 and ^{13}C - $\{^1\text{H}\}$ NOE measurements, though ^{13}C T_2 data are also accessible. For ^1H , the data set normally includes T_1 and T_2 . In analyzing relaxation data in terms of a dynamic model, it is a great advantage to have T_2 data available, since T_2 depends on the spectral density at zero frequency whereas T_1 and ^{13}C - $\{^1\text{H}\}$ NOEs depend on the spectral density only at frequencies on the order of the resonance frequencies. In ^1H NMR, data which effectively replicate T_2 by sampling the spectral density at very low frequencies on the order of differences in ^1H resonance frequencies can be obtained⁴ by measuring T_1 of one type of proton while another is kept saturated by a decoupling frequency, or by monitoring the transient NOE following selective inversion of one group of ^1H nuclei. Measurements of $T_{1\rho}$, which also monitor the spectral density at kHz frequencies, have found limited application to polymers in solution.¹⁰

3 GENERAL FEATURES OF POLYMER RELAXATION

3.1 Effect of Chain Length

Early work^{2,5} showed that for random coils in solution, relaxation times as a function of chain length attained an asymptotic value at a fairly low critical chain length on the order of 100 units, corresponding to a molar mass on the order of 10^4 . This behavior was attributed to control of relaxation above the critical length by local segmental motions independent of chain length. Below the critical length, overall molecular tumbling is sufficiently rapid to contribute to a shortening of the effective correlation time. The few exceptions to this general principle are observed for polymers which adopt a well-defined persistent conformation, such as the polypeptide α -helix. For example, measurements on poly(γ -benzyl-L-glutamate) in helix-supporting solvents show that relaxation is determined to a considerable extent by slow end-over-end and axial rotational diffusion.¹¹

3.2 Effect of Concentration

For random coil polymers, numerous studies^{2,5} have found that relaxation times are generally insensitive to concentration up to quite high values on the order of 5–10 wt.% depending on the chain chemical structure and molar mass, even though the bulk viscosity may change by several orders of magnitude. This behavior is further evidence for the control of relaxation by local segmental motions, whose rates are determined by a ‘microviscosity’ of the chain and its immediate solvent environment. At higher concentrations, the relaxation times show the effects of increasing motional hindrance, the changes in T_2 appearing at a somewhat lower concentration than those in T_1 because of the greater sensitivity of T_2 to slow long-range motions. For polystyrene in CDCl_3 ,¹² the concentration at which T_1 and T_2 become concentration-dependent depends on molar mass, and correlates with the concentration at which the chains begin to overlap.

At high concentrations, chain motion becomes restricted by physical entanglements of such severity that DD coupling is no longer averaged to zero, and strong line broadening is encountered. The spectrum exhibits a 'pseudosolid' character which may be detected in several ways, for example from the characteristic shape of the FID,¹³ or from the line-narrowing effect of sample rotation.¹⁴

3.3 Effect of Solvent

The chemical structure of the solvent affects the polymer motions in two ways,^{2,5} first dynamically through its effect on the environment 'microviscosity', and second thermodynamically through its effect on the chain conformation. In thermodynamically good solvents of comparable chemical structure, there is a reasonable consistent relationship between relaxation times and bulk solvent viscosity, as has been shown by studies of ¹³C relaxation in poly(oxyethylene)¹⁵ and poly(isoprene)¹⁶ solutions in solvents covering a wide range of viscosities. The effect of solvent viscosity on the rate of segmental motions has usually been approached through Kramers' theory¹⁷ for the rate of passage over an energy barrier E_a between two potential wells in a frictional medium. In the high-friction limit, the rate constant is given by

$$k = \frac{(\gamma_a \gamma_b)^{1/2}}{2\pi\zeta} \exp(-E_a/RT) \quad (13)$$

where γ_a and γ_b are the curvature coefficients of the potential energy at the minimum and maximum and ζ is the medium friction coefficient. Assuming that the correlation time for segmental motion, τ_c , is inversely proportional to k , the dependence of τ_c on the solvent viscosity η can then be written as

$$\tau_c = A\eta \exp(E_a/RT) \quad (14)$$

where A is a constant for a particular polymer. A plot of $\log \tau_c$ against $\log \eta$ should be linear with a slope of unity. For poly(isoprene),¹⁶ such a graph is linear, but the slope is only 0.41. A similar plot of data of poly(oxyethylene)^{15b} made by the writer gives a slope of 0.66. Thus it appears that equation (14) is better written as

$$\tau_c = A\eta^\alpha \exp(E_a/RT) \quad (15)$$

where α is an empirical exponent less than unity. Equation (15) has been rationalized¹⁶ in terms of the modification of Kramers' theory by Grote and Hynes¹⁸ in which the frequency dependence of the friction constant is taken into account. From equation (15), the Arrhenius activation energy for τ_c is equal to $E_a + \alpha E_\eta$ where E_η is the activation energy for the viscosity.

3.4 Effect of Chain Structure

In order to evaluate the effect of chemical structure on chain mobility, it is necessary to use a standard basis for the comparison. The most reliable basis is the value of nT_{1C} for protonated backbone ¹³C nuclei measured at the same resonance frequency, concentration, and temperature in good solvents of

similar viscosity. Unfortunately, such consistency in conditions is not a common feature of reported studies; however, a representative selection of values of nT_{1C} for common chain structures is given in Table 1, together with apparent correlation times obtained using equations (2) and (12).

In general, it is found that correlation times for random coil chains at ambient temperature or above lie in the vicinity of the T_1 minimum or shorter, as indicated by the facts that substantial ¹³C-{¹H} NOEs are observed and that T_1 increases with increasing temperature. The two exceptions in Table 1 are poly(4-vinyl-*N*-octylpyridinium bromide) and poly(but-1-ene sulfone). The most mobile chains are those containing a heteroatom [e.g. poly(oxyethylene)] or double bonds [e.g. poly(butadiene)], consistent with the lower barriers to rotation about CH₂-O and allylic bonds (ca. 4 kJ mol⁻¹) compared with CH₂-CH₂ bonds (ca. 16 kJ mol⁻¹). As expected, the presence of substituents decreases chain mobility, the effect increasing with the size of the substituent. However, it is perhaps surprising that two geminal substituents are not significantly more effective in hindering motion than is a single substituent [cf. poly(propylene) with poly(isobutene) or polystyrene with poly(methyl methacrylate)]. The explanation, supported by conformational calculations,¹⁹ appears to be that the introduction of a second group into the monosubstituted chains engenders such severe steric interactions that the energies of all conformations, including transition states, are raised, so leaving the barrier unaffected.

Two comparisons of pairs of polymers with similar structures but quite different relaxation times exemplify the insight into polymer conformation provided by relaxation measurements. The lower mobility of poly(oxymethylene) (POM) compared with poly(oxyethylene) (POE) has been explained²⁰ by the fact that POE has several well-populated conformations, whereas POM is substantially restricted to a single conformation, thus inhibiting segmental motions. The large difference in correlation time between the isomeric pair poly(but-1-ene sulfone) and poly(but-2-ene sulfone) has also been explained²¹ in conformational energy terms, the former predominantly occupying a *gauche* conformation with strong ordering between adjacent SO₂ dipoles and the latter predominantly occupying a *trans* conformation with independent SO₂ groups.

4 QUANTITATIVE ANALYSIS OF RELAXATION TIMES

4.1 Cross Correlation

In quantitative interpretations of relaxation in polymers, the simple Bloembergen, Purcell, and Pound approach²² has normally been used, rather than the formally correct density matrix theory²³ (see also *Relaxation Processes: Cross Correlation and Interference Terms* and *Coupled Spin Relaxation in Polymers*). An early example of a relaxation phenomenon for which the sophisticated theory is required is the observation of nonexponential T_1 relaxation of the CH₃ protons in poly(2,6-dimethyl-1,4-phenylene oxide)²⁴ which arises from a cross-correlation effect associated with very rapid internal CH₃ rotation. Recently advances in both theory and experimental techniques have been applied to the study of

^{13}C relaxation under ^1H coupled conditions in poly(ethers).²⁵ These experiments involve studying relaxation following a variety of selective and nonselective excitations of ^1H and ^{13}C transitions, and permit the determination of spectral densities for both auto- and cross-correlation functions of C–H and H–H interaction vectors, thus giving a detailed insight into the nature of chain dynamics. It is anticipated that this approach will repay further attention.

4.2 Correlation Functions for Segmental Motions

Initial investigations rapidly revealed that relaxation data for polymers could not be interpreted quantitatively using the isotropic rotation model. Even a simple measurement of the value of T_1 at its minimum at a single frequency was sufficient to show this deficiency, which is not unexpected in view of the multitude of conformational transitions available to a macromolecule. The first attempt²⁶ to rationalize data on ^{13}C T_1 and NOE values represented the segmental motions by an empirical $\log \chi^2$ distribution of exponential correlation functions, emulating the methodology which had been used for some time in dielectric and viscoelastic relaxation studies. However, while successful in allowing an interpretation of all the experimental data by a single form for the correlation function, this approach gives little insight into the nature of the segmental motions in terms of specific conformational processes.

The first general analytical expression for the NMR segmental correlation function at a molecular level was developed by Valeur et al.²⁷ using a model based on concerted motions on a diamond lattice. Only three- or four-bond segmental motions were considered, such that the remainder of the chain was

unaffected. Although the model possessed realistic elements in that the discrete jumps through realistic angles were allowed, no account was taken of possible differences in conformational probabilities, and the solution of the discrete differential equations for the bond orientational time-dependence was obtained using a continuum equation. This model, denoted the VJGM model, considered coupled motions for an infinite chain and resulted in a correlation function

$$G(\tau) = \exp(-|\tau|/\theta) \exp(|\tau|/\rho) \operatorname{erfc}(|\tau|/\rho)^{1/2} \quad (16)$$

where θ and ρ are correlation times characterizing the three- and four-bond motions and erfc represents the error function complement. The corresponding spectral density is

$$J(\omega) = \frac{2\theta\rho(\theta - \rho)}{(\theta - \rho)^2 + (\omega\theta\rho)^2} \left\{ \left(\frac{\theta}{2\rho} \right)^{1/2} \left[\frac{(1 + \omega^2\theta^2)^{1/2} + 1}{1 + \omega^2\theta^2} \right]^{1/2} + \left(\frac{\theta}{2\rho} \right)^{1/2} \left(\frac{\omega\theta\rho}{\theta - \rho} \right) \left[\frac{(1 + \omega^2\theta^2)^{1/2} - 1}{1 + \omega^2\theta^2} \right]^{1/2} - 1 \right\} \quad (17)$$

It was later recognized that although this equation resulted from a specific molecular model of conformational transitions, it represented a more general description. The terms in ρ represent cooperative processes leading to diffusion of orientation along the chain, while the term in θ also represents reorientations not necessarily linked to transitions of neighboring bonds.

The VJGM model was subsequently modified by two groups. First, Jones and Stockmayer²⁸ suggested that the three-bond motions be restricted to a finite segment of $2m - 1$ bonds on the basis that in a real chain conformational correlation

would not be strictly obeyed (the JS model). The correlation function was obtained as a discrete sum of exponentials

$$G(\tau) = \sum_{k=1}^s B_k \exp(-|\tau|/\tau_k) \quad (18)$$

with a corresponding spectral density

$$J(\omega) = \sum_{k=1}^s \frac{2B_k\tau_k}{1 + \omega^2\tau_k^2} \quad (19)$$

where $s = (m + 1)/2$ and the coefficients B_k and τ_k (tabulated in Jones and Stockmayer²⁸) depend on m .

Further modifications to the VJGM model were made by Yaris and co-workers.²⁹ They generalized the VJGM master differential equation with the explicit inclusion of a diffusion term and, recognizing that the solution of the diffusion equation is an integral of the wavevector of a plane wave, imposed both lower and upper limits on the allowed wavelengths, i.e. on the minimum and maximum size of the mobile segment.

The VJGM and JS models have been used successfully to interpret a wide range of experimental measurements of ^1H and ^{13}C relaxation parameters in a number of polymers of different backbone structure; the results have been summarized by the author.⁴ Figure 1 shows the simulation of ^1H T_1 and T_2 data for syndiotactic poly(methyl methacrylate) using the VJGM model. In general, it is found that in the VJGM model, the ratio ρ/θ lies in the range 0.1–1 and is independent of temperature. Cooperative processes dominate the chain motions. In the JS model, it is found that the values of the coupling length $2m + 1$ typically lie in the range 5–13.

Figure 1 Variation of the backbone CH_2^1H relaxation times with temperature for a 1% solution of syndiotactic poly(methyl methacrylate) in toluene- d_8 : $\circ$ T_1 at 300 MHz; $\square$ T_2 at 300 MHz; $\times$ T_1 at 80 MHz. The lines are simulations using the VJGM model, equation 13, with $\rho/\theta = 0.7$. (Reproduced by permission of Pergamon Press from Heatley⁵)

In recent years, increases in computing power have allowed more realistic investigations of polymer dynamics using two approaches, first molecular dynamics simulations,³⁰ and second time-dependent rotational isomeric state (RIS) statistical theory.³¹ The dynamics simulation technique generally involves numerical solution of the Langevin equation of motion of a chain of atoms moving in a viscous medium subject to forces from bond rotations, bond stretching, and bond angle bending, as well as a random Brownian force. A significant result is that rotations about one bond only are not as hindered as might be expected by the fact that such a motion necessarily requires the long polymer ‘tails’ to move through the medium. Evidently the movement of the tails is initially accommodated by elastic distortion of neighboring bond torsion angles. The simulations also show that the correlation function depends on the orientation of the vector relative to the chain backbone,^{30a} indicating that the correlation function for ^1H relaxation may be different to that for ^{13}C relaxation. In heterogeneous chains, e.g. polyisoprene,^{30c} C–H bonds in different groups are found to have different correlation functions, consistent with the experimental observation of different values of nT_{1C} . It has been shown^{30a,32} that numerically simulated correlation functions are well represented by the following analytic expression (the HWH model)

$$G(\tau) = \exp(-|\tau|/\tau_0) \exp(-|\tau|/\tau_1) I_0(|\tau|/\tau_1) \quad (20)$$

where I_0 is the Bessel function, and τ_0 and τ_1 are correlation times representing single-bond and cooperative transitions, respectively. The spectral density is

$$J(\omega) = 2(\alpha^2 + \beta^2)^{-1/4} \cos \left[\frac{1}{2} \arctan \left(\frac{\beta}{\alpha} \right) \right] \quad (21)$$

where $\alpha = \tau_0^{-2} + 2(\tau_0\tau_1)^{-1} - \omega^2$ and $\beta = 2\omega(\tau_0^{-1} + \tau_1^{-1})$.

Although the various expressions for the correlation function given above differ markedly in mathematical form, it has been found in practice that with suitable choice of parameters they coincide closely in shape,⁴ and experimental results can often be satisfactorily simulated by different models.³³

The RIS theory expresses both conformational and transition probabilities by matrices whose order is determined by the degree of conformational and dynamic interdependence of the chain bonds. The general solution leads³⁴ to a correlation function expressed as a discrete distribution of exponential functions. The method is capable of embodying the characteristic properties of a particular chain, and calculations have been carried out for several chains whose conformations are well-understood, including polyethylene³⁵ and poly(oxyethylene).³⁶ For polyethylene,³⁵ it was found that the results from RIS calculations could be well-represented by the JS or HWH functions. For poly(oxyethylene),³⁶ the RIS theory was combined with Kramers’s theory¹⁷ of the medium effect on transition rates [equation (11)] to calculate a priori the effect of solvent viscosity on ^{13}C correlation times: the results were in good agreement with experiment.

4.3 Other Polymer Motions

4.3.1 Librations

In polymers known to have a relatively persistent conformation, such as the fixed conformation of biological

Figure 2 Values of nT_{1C} for ^{13}C nuclei in poly(*N*-hexyl-4-pyridinium bromide) at 25.14 MHz in CD_3OD at 26 °C. (Data from Radiotis et al.³⁹)

macromolecules, or the helical structure of regular polypeptides in some solvents, it has been found³⁷ that in order to understand relaxation parameters quantitatively, it is necessary to include a high-frequency limited-amplitude libration arising from vibrations and torsional oscillations. This motion has also been found necessary to understand relaxation in molten synthetic polymers,³⁸ and it is also manifest in dynamics simulations.^{30c} The motion is much more rapid than segmental motions, and falls into the extreme narrowing regime. It is usually modeled³⁸ by the 'diffusion-in-a-cone' model in which the internuclear vector diffuses freely within a cone of semi-angle ϕ , while the axis of the cone undergoes reorientation according to the dynamics of the backbone. The appropriate correlation function is

$$G(\tau) = A \exp(-|\tau|/\tau_v) + (1 - A)G_b(\tau) \quad (22)$$

where τ_v is the libration correlation time and $G_b(\tau)$ is the segmental correlation function given by one of the expressions above. The quantity A expresses the loss of correlation by the libration and is related to ϕ by

$$A = 1 - \left[\frac{\cos \phi - \cos^3 \phi}{2(1 - \cos \phi)} \right]^2 \quad (23)$$

Recent work, for example a study of multiple-frequency ^{13}C relaxation data for poly(vinyl chloride) in solution,³⁹ has shown that the combination of equations (20) and (23) generally gives the best fit to experimental data. Typically, $\phi \approx 30^\circ$ and $\tau_v \approx 10^{-12}$ s.

4.4 Side-Chain Motions

Generally, nuclei in side chains have shorter average correlation times than backbone nuclei because internal rotation of the side group is commensurate with or faster than segmental motions.²⁻⁵ As an example, Figure 2 illustrates the positional dependence of ^{13}C T_1 values in poly(*N*-hexyl-4-pyridinium bromide) in CD_3OD .⁴⁰ Quantitatively, multiple internal rotations have been modeled by stochastic, independent, rotational diffusion about successive bonds,⁴¹ though for aromatic rings a model of restricted rotation has proved more appropriate.⁴²

1 INTRODUCTION

For many engineering applications of polymeric materials it is important to know how the material behaves under elastic or plastic deformation. Since the mechanical properties of such a material are a consequence of the chemical composition and the physical microstructure of the material, it should be possible in principle to predict the mechanical properties from the microscopic structure. However, especially for heterogeneous polymeric materials (copolymers, polymer blends and polymer composites) a complete prediction of the behavior under mechanical stress, starting from the microscopic structure, is still too difficult. Therefore experimental techniques are necessary, which allow the detection of changes in the microstructure when the material is mechanically deformed.

In a polymeric material under stress the polymer chains can react to the stress by changing their orientation, their conformation, their mobility or even by breaking. Although many techniques exist which can probe microscopic changes in a polymer material, the advantage of NMR to study materials under stress is that NMR is able to detect the effect of stress on the structure of a material on a molecular level. On the other hand, the combination of the NMR technique, where usually the sample is located in a strong magnetic field, and the devices to mechanically deform materials, in general do not form great combinations. Therefore a great number of NMR publications deal with the study of polymeric materials, which have *prior* to the NMR experiment undergone some kind of deformation by a mechanical force. The NMR is performed on samples in the relaxed state, which may be quite different from the state of the material under tension.

Also to keep the size of this paper within certain limits, we only review here those NMR experiments on solid or gel-like materials where the material is under mechanical tension *during the NMR experiment*. We therefore also exclude the many NMR experiments on polymer melts or polymer solutions. In other words, we limit ourselves to NMR experiments where the probe head contains a device to keep the sample under stress.

This restriction implies that in most of these experiments the information has to come from a wide-line NMR spectrum, usually either from a wide-line proton spectrum or from a deuterium spectrum. Exceptions are investigations on elastomers, where the high polymer chain mobility provides high-resolution spectra for spectroscopic studies or allows standard imaging NMR techniques, and experiments where the sample under stress is contained in a magic angle rotor so that high-resolution ^{13}C CPMAS techniques can be used. For this reason most experiments which we will summarize, are experiments on elastomers.

After a short introduction to the macroscopic theory of polymer deformation, the paper is divided in two sections: NMR spectroscopy and NMR imaging. The spectroscopical section is subdivided with respect to the nucleus investigated: proton, deuterium or carbon-13.

2 A SIMPLE INTRODUCTION TO THE DEFORMATION THEORY OF SOLID POLYMERS AND CONSEQUENCES FOR NMR

In this section we want to give a short introduction to the main notions of deformation theory and summarize those macroscopic aspects that are important to understand the results discussed here. For an introduction to the mechanical properties of solid polymers, see for instance the textbook by Ward and Hadley.¹

For an ideally elastic rectangular or cylindrical solid rod with a cross-section area A and length ℓ , subjected to a force F in the length direction of the rod, the strain ε is proportional to the stress σ :

$$\sigma = E\varepsilon \quad (\text{Hooke's law}) \quad (1)$$

Here $\sigma = F/A$, $\varepsilon = \Delta\ell/\ell$ and E is the elasticity modulus (or Young's modulus).

Although for small strains many polymeric materials behave elastically, in general E is dependent on ε . Typical stress-strain curves for different types of polymers are shown in Figure 1. Also for most polymers E shows a characteristic temperature dependence, see e.g., Figure 2 for an amorphous polymer. At temperatures $T < T_g$ (T_g is the glass-transition temperature) the material of Figure 2 is in a glassy rigid state with elastic behavior. Above T_g to a first approximation the material behaves rubbery and at temperatures above T_m (T_m = melting temperature) viscous flow is observed. A more detailed view at the temperature regime $T_g < T < T_m$ reveals that the material does not show ideally elastic behavior but also has viscous properties. The polymer is in a visco-elastic state, which is in between the ideal Hookian behavior (stress proportional to strain) and the ideal Newtonian flow of a liquid (shear stress proportional to the shear rate). For visco-elastic polymers the stress and strain curves are time dependent, which

Figure 1 Schematic stress-strain curves for glassy and rubbery polymers (elastomers). For small strain values the slope of the curves represent the elastic modulus E

Figure 2 The temperature dependence of the elastic modulus E for a typical non-cross-linked polymer. Below T_g the polymer is glassy with a high E (see also Figure 1), between T_g and T_m the polymer shows visco-elastic behavior and above T_m the polymer is viscous

Figure 3 A schematic representation of visco-elastic behavior: (a) at a sudden increase of the stress at $t = 0$ to a constant value, the elongation ε follows with a time lag (creep). An ideally elastic solid would show an immediate constant elongation. (b) After a stepwise increase of the elongation ε , the stress decreases in time (relaxation). An ideally elastic solid would show a constant stress value

results in creep and relaxation phenomena, as schematically shown in Figure 3.

The complex response of a polymer to mechanical stress will result in changes of some NMR parameter. A complete description of the effect of stress or strain on NMR parameters is a formidable theoretical problem. To realize the difficulty of this problem let us consider the following example. We will see later that for spectroscopic studies, as well as in NMR imaging experiments, the NMR parameter that is often used to monitor the strain or stress in a material, is the proton T_2 . The proton

T_2 in a not completely rigid material depends on anisotropic molecular motions, for instance in a cross-linked polymer the hindered rotations and translations of those segments of the polymer chain between the cross-linked joints.

By applying stress to a heterogeneous polymeric material a spatially dependent deformation with tensorial character develops. To predict the effect of this deformation on the proton T_2 , it would be necessary to calculate how the local anisotropic molecular motions are affected by the anisotropic deformation and then how the changed molecular motions influence the proton dipolar interactions. The result of the interplay between all these tensorial interactions is finally monitored by the *scalar* parameter T_2 . It will be clear that in practice a theoretical description has to be simplified.

The intermediate visco-elastic state between the low temperature glass state and the high temperature molten state is a rubbery phase. In this state a small stress causes a very large extension. When a material in the rubbery state is extended, the restoring force is mainly due to the change in entropy and not, like for steel, due to a change in the internal energy. It can be shown from thermodynamic arguments that for an incompressible cross-linked rubber material at constant temperature the tensile stress σ is given by:¹

$$\sigma = \frac{\rho RT}{M} \left(\lambda - \frac{1}{\lambda^2} \right) \quad (2)$$

where $\lambda = \ell + \Delta\ell/\ell = 1 + \varepsilon$, M is the mean molecular mass between cross-links and ρ the density of the polymer. Equation (2) reduces to equation (1) for small strains for which $\lambda \approx 1$.

For an incompressible solid a small elongation by $\Delta\ell$ reduces the cross-section area from A to A/λ . When the stress is referred to the original cross-section area A in the absence of stress ('engineering' or 'nominal' stress), equation 2 changes to:

$$\sigma' = \frac{\rho RT}{M} \left(\lambda^2 - \frac{1}{\lambda} \right) \quad (3)$$

For polymers in the rubbery phase usually the chains are very mobile. This can be easily experimentally observed when the chains contain proton or deuteron spins. At a temperature below T_g the proton NMR spectrum will be very broad due to the dipolar interactions between the spins. In the case of deuterium spins the spectrum will show the well-known Pake-doublet line shape of deuterium in a non-ordered rigid solid. For temperatures above T_g the chain mobility can be so high, that the dipolar or quadrupolar interaction is averaged to a very small value, resulting in spectra with a single narrow line.

3 SPECTROSCOPICAL STUDIES OF DEFORMED POLYMER MATERIALS

3.1 The Effect of Mechanical Tension Studied by Proton NMR

In the proton NMR studies of deformation in polymeric materials the attention is focussed on the transverse magnetization decay, as measured by the free induction decay (FID) or by a spin-echo experiment. It is assumed that the proton

transverse relaxation is fully governed by the proton dipole-dipole interactions, possibly reduced by the rotational motions of the chain segments.

Different general theories exist that describe the transverse relaxation in the presence of molecular motions. The usefulness of these theories can be classified with the help of a motional correlation time τ_c , which is here very loosely defined as the characteristic time lap during which the rotational or translational coordinates of a molecular segment have changed so much by random molecular motions that there is no resemblance to the coordinates of the initial state anymore. This motional correlation time varies strongly when we go from a rigid solid, where $\Delta\omega_H\tau_c \gg 1$ ($\tau_c \gg 10^{-5}$ s, $\Delta\omega_H$ is the rigid-lattice proton line width), to a liquid of small molecules, where $\omega_0\tau_c \ll 1$ ($\tau_c \ll 10^{-9}$ s, ω_0 is the resonance frequency).

The Bloch-Wangness-Redfield theory² is valid in the range between complete motional averaging ($\omega_H\tau_c \ll 1$) and beyond extreme motional averaging ($\omega_0\tau_c \ll 1$). In this range the transverse magnetization decays exponentially with a characteristic time T_2 :

$$M(t) = M(0) \exp\left[-\frac{t}{T_2}\right] \quad (4)$$

representing a Lorentzian line shape in the frequency domain.

For incomplete motional averaging, when the condition $\omega_H\tau_c \ll 1$ is not fulfilled, the Anderson-Weiss³ and the Kubo-Tomita⁴ theories can be applied. Although these two theories have a different theoretical basis, they both lead to the same expression for the transverse relaxation function:

$$M(t) = M(0) \exp\left[-(\Delta\omega_H)^2 \int_0^t (t-\tau) g(\tau) d\tau\right] \quad (5)$$

where $g(\tau)$ is a normalized correlation function, $g(0) = 1$.

When an exponential correlation function is assumed:

$$g(\tau) = \exp\left[-\frac{\tau}{\tau_c}\right] \quad (6)$$

Equation 5 reduces to:

$$M(t) = M(0) \exp\left[-(\Delta\omega_H)^2 \tau_c^2 \left\{\exp\left[-\frac{t}{\tau_c}\right] + \frac{t}{\tau_c} - 1\right\}\right] \quad (7)$$

In the case where the correlation time $\tau_c \gg t$, t being the length of the FID (no motions), we find the rigid lattice limit by expanding $\exp[-t/\tau_c]$ in a power series:

$$M(t) = M(0) \exp\left[-\frac{1}{2} (\Delta\omega_H)^2 t^2\right] \quad (8)$$

This Gaussian decay function represents a Gaussian solid state NMR line.

In the motional averaging limit $\Delta\omega_H\tau_c \ll 1$ the integral in equation (5) can be written as:⁵

$$\int_0^t (t-\tau)g(\tau) d\tau \approx t \int_0^\infty g(\tau) d\tau = \tau_c t \quad (9)$$

which yields a Lorentzian line shape:

$$M(t) = M(0) \exp\left[-(\Delta\omega_H)^2 \tau_c t\right] \quad (10)$$

with the reduced line width

$$\frac{1}{T_2} = (\Delta\omega_H\tau_c)\Delta\omega_H \quad (11)$$

Most polymer materials behave like a network in which the chains are cross-linked, either by covalent bonds, as in vulcanised rubber, or by physical cross-links like entanglements or crystalline domains. With respect to the general relaxation theories summarized above, such network polymers constitute a special class of materials, since they can reflect both solid-like and liquid-like behavior at the same time. For a cross-linked polymer below T_g the FID is that of a strongly dipolar coupled rigid proton spin system (equation 8). Above T_g those parts of the chains relatively far from the junctions can execute fast, almost isotropic motions (liquid-like behavior), while the motion of those parts of the chains near cross-links is severely hindered (solid-like behavior). In addition some chains may exist (dangling ends) which are joined to the network by one end only and it can be expected that these chains are even more free to move than the segments between cross-links.

The transverse magnetization decay function $M(t)$ of such a network reflects the mobility of all parts of those chains and therefore it can be expected that the general relaxation theories discussed above are not able to accurately describe the transverse magnetization decay. Indeed, several special transverse relaxation functions have been used for polymers.

In the work of Simon et al.⁶ a Bloch type exponential relaxation decay (equation 4) was assumed for the dangling ends and an Anderson-Weiss/Kubo-Tomita type decay (equation 7) for the chains between two cross-links.

A completely different approach was taken by Sotta et al.⁷ who realized that for a polymer network transverse relaxation is not only caused by irreversible ('homogeneous broadening') processes due to chain mobility, as we discussed above, but that due to the constraints by the chain junctions the local dipolar interactions are not averaged to zero. This causes a spread in resonance frequencies ('inhomogeneous broadening'). High enough above T_g these authors assume that the decay induced by the chain motions is so much slower than the decay due to the residual local dipolar field that only the heterogeneous contribution has to be considered. From a statistical analysis they found for polymer chains consisting of N segments, each segment carrying one isolated proton pair with dipolar coupling strength Δ :

$$M(t) = \text{Re} \left[\frac{M_0}{\left(1 + \frac{1}{3} ikN^{-1}\Delta t\right) \sqrt{1 - \frac{2}{3} ikN^{-1}\Delta t}} \right] \quad (12)$$

where k is a geometrical factor.⁸

After summarizing some different expressions for the decay of transverse magnetization we review the results of typical proton NMR experiments on polymers under tension.

Nishi and Chikaraishi⁹ investigated the transverse magnetization decay of cross-linked natural and synthetic rubber samples as a function of cross-link density for various elongations. By fitting their results with equations (4) and (11) they found that T_2 depends on the elongation factor λ mainly via the dependence of the correlation time τ_c on λ , the dependence

of the rigid-lattice line width on stretching was small. The λ -dependence of T_2 could be fitted with an empirical relation of the form:

$$T_2(c, \lambda - 1) = T_{2,0}(c) \exp[-kc(\lambda - 1)] \quad (13)$$

where c is the crosslink density, $T_{2,0}$ the T_2 in the absence of deformation and k a constant (1.1×10^3 cc/mol). This shows that mechanical tension on a polymeric material can influence the chain mobility. Here τ_c increased with tension, probably due to the fact that the stretching of the rubber induced crystallization, as is apparent from the fact that at $\lambda > 5$ a second component in the FID appears with a much shorter T_2 . In one of the next subsections we will consider this strain-induced crystallization in more detail.

Fukumori et al.¹⁰ studied a styrene-butadiene-styrene (SBS) blockpolymer. Here the rigid styrene blocks act as physical crosslinks or 'hard' segments in the rubbery polybutadiene matrix. Also here a dependence of T_2 on λ as shown in equation (13) was found.

Another approach to the dependence of the transverse magnetization decay on stretching was followed by Cohen-Addad and Huchot.¹¹ They found for vulcanized polybutadiene of different chain lengths and cross-link density c that the initial slope s of the proton magnetization decay at time $t = 0$ is given by:

$$s = s_0 + \left(\lambda^2 - \frac{1}{\lambda} \right) \left| 3 \cos^2(\theta) - 1 \right| \kappa(c) \quad (14)$$

where $\kappa(c)$ is a function of the cross-link density c and s_0 the slope observed in the absence of any deformation. The angle θ is the angle between the stretching direction and the magnetic field. Figure 4 shows how well the experimental results on vulcanised polybutadiene fit equation (14). Equation (14) shows the same dependence on the stretching variable λ as the stress referenced to the original cross-section area, equation (3).

Equations (13) and (14), however, are not completely identical, which becomes clear when the initial slope of the free induction decay in the motional averaging limit is related to T_2 according to equation (4):

$$s = -\frac{M_0}{T_2} \quad (15)$$

With equation (15) we can rewrite equation (13) in a form which can be directly compared to equation (14):

$$s = s_0 \exp[kc(\lambda - 1)] \quad (16)$$

Although equations (14) and (16) are not identical, for certain values of k , c and $\kappa(c)$ and a limited range of λ -values their λ -dependences are similar.

Figure 4 (a) The stress ratio σ/σ_0 of vulcanised polybutadiene as a function of the stretching parameter $\lambda^2 - 1/\lambda$ for vulcanized polybutadiene for different molecular weights and/or sulfur concentration c : open and filled circles $\overline{M}_n = 2.5 \times 10^5$, $c = 1\%$; open and filled triangles $\overline{M}_n = 3.6 \times 10^5$, $c = 0.5\%$; open and filled diamonds $\overline{M}_n = 2.5 \times 10^5$, $c = 0.5\%$. Open symbols correspond to $\theta = \pi/2$, while for closed symbols $\theta = 0$, where θ is the angle between the stretching direction and the magnetic field. (Reproduced with permission from Cohen-Addad and Huchot¹¹)

Cohen-Addad and Huchot¹¹ conclude further from their experiments on several vulcanised systems that the elasticity modulus E is proportional to the factor $\kappa(c)$ from equation (14). Therefore the slope of the curves in Figure 4a is proportional to E .

3.2 Deuterium NMR

^2H is by far the most popular NMR nucleus to study the effect of deformation on the molecular orientation and motions in polymer systems. The reason is that the characteristic quadrupole broadened deuterium NMR spectrum for randomly oriented rigid polymer chains ('Pake doublet') can be strongly and characteristically affected by molecular orientation and/or molecular motions, effects which can both be induced by mechanical deformation. In addition, the simulation of a motionally averaged spectrum or the spectrum of partly oriented samples is relatively easy, so that order parameters and/or motional parameters can be determined from the experimental spectra.

3.2.1 The Effect of Deformation on Molecular Motion

The first example of the effect of in-situ stress on NMR parameters was published by Hansen et al.¹² who investigated

Figure 4 (b) The stress ratio σ/σ_0 of vulcanized polybutadiene as a function of the stretching parameter $\lambda^2 - 1/\lambda$ for vulcanized polybutadiene for different angles between the stretching direction and the magnetic field. The molecular weight $\bar{M}_n = 2.5 \times 10^5$. (Reproduced with permission from Cohen-Addad and Huchot¹¹)

phenylene ring flips in polycarbonate as a function of the applied stress. A pneumatically driven stretching apparatus,¹³ good for forces up to 1500 N, could be triggered by the spectrometer software to synchronize rf pulsing and the application of stress. The effect of the applied stress was monitored by ^2H two-dimensional exchange spectroscopy¹⁴ and echo experiments. In polycarbonate the phenyl rings can make 180° flips. By simulation of the experimental 2D-exchange spectra it was found that prior to a flip the ring executes small angle rotations and also that the ring flip angle is not always exactly 180° . The main results of Hansen et al. are reproduced in Figure 5. This figure shows the remarkable result that the width of the distribution of the phenylene ring small angle rotations before a flip is independent of the applied stress, while the width of the distribution of the flip angles itself, with a mean value of 180° , increases with stress. Apparently, the application of stress loosens the angular restriction for the ring flip, allowing larger deviations from 180° than in the absence of an applied stress. At the same time echo experiments have shown that the distribution of correlation times of this motion is not affected by the stress. Here stretching does not increase the motional correlation time, as in one of the examples of section IIIa, but stretching does enhance deviations from the average flip angle 180° .

Schaefer et al.¹⁵ also conclude that stress enhances the phenylene ring flip motion in poly(*p*-phenyleneterephthalamide) fibers. These authors lead a suspended bundle of fibers through a 5 mm saddle-coil in the probe head. The bundle can be loaded with 31 steel (!) plates to a total weight of 300 kg, which causes an elongation of ca. 1% at 55% of the breaking stress.

Figure 5 Distribution of the flip angles of the phenylene ring in polycarbonate for the unstretched and the stretched sample. (Reproduced with permission from Hansen et al.¹²)

Another example of the use of deuterium NMR to investigate the chain mobility in polymers under stress was reported by Loo et al.¹⁶ Here polyamide-6 rods were deuterated by immersing the rods in D_2O for several weeks. By H-D exchange between D_2O and nylon-6 it is assumed that only the polyamide N-H groups in the amorphous domains were deuterated. The experiments show that at 70°C , which is near T_g , the mobility of the chains in the amorphous regions is increased by stretching. At room temperature such an effect is not observed.

3.2.2 The Effect of Deformation on Orientation

Two approaches have been followed to study the effect of mechanical deformation on the polymer chain orientation, the deuterium atoms are part of small solvent molecules which are absorbed by the polymer system (swelling) or the polymer chains itself are (partly) deuterated. In the first case, in general the solvent molecules are highly mobile and the quadrupolar spectrum does not show a splitting, but is broadened by T_2 effects as described in section IIIa. When the polymer material is stretched, the rotational diffusion of these molecules becomes non-isotropic and this results in a quadrupolar splitting $\Delta\nu$.¹⁷

$$\Delta\nu = \frac{3e^2qQ}{2h} \left(\langle P_2(\cos\theta) \rangle + \frac{1}{2}\eta \langle \sin^2\theta \cos 2\phi \rangle \right) P_2(\cos\Omega) \quad (17)$$

where:

$\frac{e^2qQ}{h}$ = quadrupolar coupling constant

η = quadrupolar asymmetry parameter, usually $\eta \approx 0$

θ, ϕ = the polar angles between the C-D bond and the stretching direction

Ω = angle between the stretching direction and the magnetic field and,

$\langle \rangle$ = averaging over all angles.

Equation 17 shows that the resulting quadrupole splitting is proportional to the average order parameter S if $\eta = 0$:

$$S = \langle P_2(\cos \theta) \rangle = \frac{1}{2} \langle (3 \cos^2 \theta - 1) \rangle \quad (18)$$

Theoretically¹⁸ it has been shown that for ideally elastic polymer networks S is proportional to $E(\lambda^2 - 1/\lambda)$, where E is the modulus. Many authors^{19,20} indeed confirmed experimentally that the residual quadrupolar splitting $\Delta\nu$, induced by uniaxial stretching of an elastic polymer network depends on the stretching constant λ as:

$$\Delta\nu \propto \left(\lambda^2 - \frac{1}{\lambda} \right) \quad (19)$$

Figure 6 The deuterium spectra of cross-linked polybutadiene as a function of the elongation factor λ . (Reproduced with permission from Ries et al.²⁰)

where the stretching variable is the same as in equation (3) (see Figure 6).

When a network is deformed, the spatial positions of the network junctions are changed and one might expect that the anisotropy caused by these displacements is the cause of the induced quadrupole splitting. However, Brereton²¹ theoretically studied ideal networks in which the chains between junctions are free to move and do not interact with each other. He found that the displacement of the chain junctions in the network by the mechanical deformation was not sufficient to obtain a quadrupolar splitting. A splitting of the line shape of deuterons in the chains of the network is induced by an uniaxial deformation only when interactions between the chain segments in the network are introduced. This result was confirmed by Warner et al.²²

When the deformation of a polymer network is probed by an absorbed solvent molecule, an important question here is in how far the solvent molecule and the network have the same degree of orientation. This problem was tackled by Jacobi et al.²³ who showed for cross-linked deuterated polybutadiene, swollen to different degrees by free deuterated butadiene oligomers, that for low degrees of swelling the orientation of the solvent molecules and of the network as a function of uniaxial strain are the same. For larger fractions of solvent molecules, however, the orientation of the oligomers is considerably lower than that of the network. Two explanations have been offered for the experimental observation that solvent molecules with the *same* chemical composition as the network molecules follow the orientation of the deformed network. The first explanation assumes an interaction like between the molecules in a nematic liquid crystal, the second suggests that competition for space causes an orientational coupling due to entropic interactions.^{24,25} Experiments by McLoughlin et al.¹⁹ seem to confirm the latter explanation.

An example of the use of small deuterated molecules in deformed samples forms the work by Loo et al.²⁶ Here polyamide-6 is investigated by letting phenol-d₅ from the solvent CCl₄ diffuse into the amorphous domains of the polymer. Since it is known that phenol plasticizes polyamide-6 it is the combination of polyamide-6 with phenol (the investigated polyamide contained 40% wt phenol) that is been investigated, not the polymer itself. The deuterium quadrupole spectrum of phenol-d₅ was recorded as a function of an elongation up to twice the original length, see Figure 7. By deconvoluting the spectra reproduced in Figure 7 with two Lorentzians, the authors found that the quadrupole splitting, as defined by equation (18), of the phenol deuterons in the amorphous domains of polyamide-6 approximately increased linearly with the strain, while the line widths showed an S-shaped relation with strain. This difference in behavior of the quadrupole splitting and the deuterium line width as a function of strain can be due to the difference in the local property that is probed by the quadrupole interaction. For the quadrupole splitting the average orientation of the probe molecule is important, for the line width the motional correlation time is decisive.

The near proportionality between the quadrupole splitting $\Delta\nu$ and the strain in this work clearly deviates from the quadratic dependence shown in other elastomer networks (equation 19), although the crystalline domains in the polyamide-6 material can be considered as the physical junctions in a network of plasticized amorphous chains.

Figure 7 The deuterium spectra of phenol-d₅ in polyamide-6 rods undergoing an elongation with a rate of 0.25 mm/min. (Reproduced with permission from Loo et al.²⁶)

In the investigations discussed above, the polymer networks were considered to be homogeneous in the way that all chains were cross-linked on both ends. In more recent work the magnetization decays are decomposed into two fractions. One fraction results from chains that are cross-linked at both ends, intercrosslinked chains, the other fraction from dangling ends. It was assumed that the dangling ends (and possibly some free chains) can reorient isotropically and their magnetization decay is represented by an exponential decay with relaxation time T_2 . The decay of the intercrosslinked chains is represented by a relation like shown in equation (7).

Using such a decomposition, Menge et al.²⁷ related for partly deuterated polybutadiene the polymer segment order parameter S with the stretching parameter, for both the intercrosslinked and the dangling chains. Figure 8 shows a linear relation between the stretching parameter and S , but with different slopes for the intercrosslinked and the dangling chains.

Figure 8 Dependence of the deuterium splitting $\Delta\nu$ as a function of the stretching parameter $\lambda^2 - 1/\lambda$ for two components with different T_2 in polybutadiene networks; $\blacklozenge$ represent the chains cross-linked at both ends with short T_2 , $\blacksquare$ stands for pendant chains with a long T_2 . (Reproduced with permission from Menge et al.²⁷)

Also it was found that the line width of the intercrosslinked chains increased strongly with stretching (meaning an increase of the correlation time τ_c , see equation (7)), in contrast to the line width of the dangling ends, which remained constant.

Thus far we discussed experiments where the stress during the NMR experiment was considered to be constant. NMR, however, is also able to follow the time-dependent mechanical relaxation behavior after a stress step. In experiments by Dardin et al.²⁸ on elastomers networks in which the cross-linking was performed by hydrogen bonds between units randomly attached to partly deuterated polybutadiene chains, the stress relaxation could be followed in time by the slow decrease of the quadrupole splittings. Figure 9 shows the decrease of the deuterium quadrupole splitting of such a network as a function of time.²⁸ The quadrupole splitting disappears with time, evidently due to a gradual breakdown of the hydrogen bonded junctions.

Figure 9 Decrease of the relative deuterium quadrupole splittings $\Delta\nu_{\text{rel}}$ as a function of time in a polybutadiene network where the cross-links are formed by hydrogen bonds between units randomly placed along the polybutadiene chains, for two different initial elongations $\lambda = 2.2$ ($\blacksquare$) and $\lambda = 3.1$ ($\circ$). (Reproduced with permission from Dardin et al.²⁸)

3.3 ^{13}C NMR

At first sight ^{13}C NMR seems not the best nucleus for NMR experiments on polymers under tension. Because of experimental reasons most combinations of mechanical deformation and NMR rely on the dependence of some anisotropic spin interaction on deformation. Anisotropic spin interactions are sensitive to both molecular rotations and orientation and therefore provide evidence of the effect of sample deformation on molecular mobility and orientation. As discussed above, for proton spins the proton-proton dipolar interaction and for deuterium the quadrupole interaction is used. For ^{13}C NMR in principle the ^{13}C chemical shift anisotropy or the proton-carbon dipolar interactions are available and could be employed in the same way as for instance for protons. At this point we have not discussed an example where the isotropic chemical shift is used, although the isotropic chemical shift is a parameter which depends on the local structure, much more so than the dipolar interactions or the quadrupole interaction. A disadvantage of the isotropic chemical shift is that its value is hardly affected by molecular motions or orientations.

The problem with using isotropic chemical shifts is that the line broadening effects of the anisotropic interactions, like the dipolar interactions or the chemical shift anisotropy, have to be eliminated. In other words, solid state high resolution techniques like magic angle spinning have to be used.

The combination of a stretching device and a magic angle rotor is not an easy combination. However, it has been shown by Schmidt et al.²⁹ that it is possible to bring prestretched samples *under stress* into a standard magic angle rotor (see Figure 10). Standard CP-MAS³⁰ experiments can then be performed as a function of the stress. The advantage of this method is that, without the need for preparing selectively deuterated samples, the high resolution CP-MAS spectrum under stress provides information about the effect of mechanical deformation on each chemical group in the material that causes a distinguishable ^{13}C NMR line.

Schmidt et al.²⁹ investigated materials composed of semi-crystalline block copolymers of poly(butylene terephthalate) (PBT) and poly(tetramethylene oxide) (PTMO). In this thermoplastic copolymer material the PBT segments form hard, crystalline blocks in a soft amorphous matrix of PTMO and PBT. The experiments have shown that the amorphous matrix is phase-separated into a very mobile PTMO-rich phase and a PBT/PTMO mixed phase with restricted mobility. It is clear that these block copolymers can again be considered as a network where the PBT crystalline domains form the physical cross-links. This material is a typical example of modern polymeric materials, in which two components are combined to form a cross-linked elastomer which can be melted.

Figure 11 displays the effect of increased strain on part of the ^{13}C CP-MAS spectrum of the PBT/PTMO copolymer. The spectra of the sample, which is transferred to the rotor in the way depicted in Figure 10 ('in-situ stretched') and of the samples brought into the rotor after the samples were allowed to relax after stretching ('stretched') can be compared. Upon stretching a new resonance for the PTMO OCH_2 carbons shows up at 72.5 ppm, shifted by ca. 1.3–1.4 ppm down field relative to the corresponding peak of the unstretched material, and with an intensity proportional to the strain. This peak is assigned to crystalline PTMO, which is induced by the stretching. It is found that the strain-induced crystallization depends on the temperature and on the PTMO block length.

Figure 10 A schematic representation how a sample under stress is transferred from the stretching machine into a standard 7 mm magic angle rotor. (Schmidt et al.²⁹)

Figure 11 ^{13}C CP-MAS spectra of PBT/PTMO copolymers as a function of the elongation factor ε . The 'stretched' spectra result from samples stretched before the measurement and then relaxed, the 'in-situ stretched' spectra are from samples under stress in the rotor. (Schmidt et al.²⁹)

4 NMR IMAGING OF POLYMERS UNDER TENSION

NMR imaging finds most of its applications in medical diagnostics but can also be used for materials science.^{31,32} The spatial resolution of an NMR imaging experiment is dependent on the width of the resonance line,³³ the smaller the line width, the higher the obtainable resolution. Therefore

NMR imaging is particularly useful for elastomers, where the molecular motions are so fast that the rigid solid state line width for protons or deuterons is reduced to values comparable to those of solution NMR. Nevertheless the spatial resolution usually is not better than ca. 100 μm .

Although with respect to spatial resolution NMR imaging is unattractive when compared to other modern microscopical techniques, like e.g., atomic force microscopy, NMR imaging also has some definite advantages:

- (a) the large number of parameters which can be used to obtain image contrast and
- (b) the fact that NMR imaging can be used to image the inside of materials in a non-invasive way.

As remarked above, in the imaging of elastomers it is very helpful that the high molecular mobility at temperatures above T_g strongly reduces the proton line width. On the other hand, by using contrast filters based on residual dipolar interactions, the experiments can be modified in such a way that those parts of the sample with residual dipolar interactions are represented in the image. Among the various contrast parameters for such experiments the proton transverse relaxation time T_2 is particularly important, while it can easily be used to discriminate between more rigid-like and more liquid-like domains, since the value depends on the motional correlation time τ_c , as discussed in section 3.1. Another contrast technique, which also depends on the polymer chain mobility and residual dipolar interactions, is multi-quantum filtering. In chains of elastomers not undergoing fast isotropic motions, the dipolar interactions, especially within CH_2 and CH_3 groups, are not completely averaged out and therefore single and double quantum coherences can be generated. The contrast parameter to be used of course has to be dependent on stress, but both T_2 and multi-quantum filtering fulfil this condition.

A beautiful example of NMR imaging of materials is the imaging of the distribution of strain in a polymer material. NMR imaging in this sense is comparable to certain optical techniques (polariscope, Moiré method), which are used to image strain in optically transparent materials,³⁴ except that, obviously, for NMR the material does not need to be optically transparent. An example of the imaging of strain is reproduced in Figure 12, where a double-quantum-filtered proton image of a stressed rubber band with a cut is presented.³⁵

A different possibility is the imaging of the temperature profile of a polymer material, which arises when the material

Figure 12 ^1H -NMR image of a rubber band with cut under stress. (Reproduced with permission from Demco et al.³⁵)

is subjected to a dynamic deformation. When the T_2 value is temperature dependent, the T_2 profile of the material represents the spatial changes of the value of the loss module,³⁶ since the loss module determines the amount of heat generated by a dynamic deformation. Another important development by Blümich et al. is a mobile surface NMR sensor ('NMR mouse'), which can be used to determine the stress behavior of arbitrarily large objects.³⁷

5 CONCLUSIONS

Although certainly not all examples of the use of NMR for the study of polymeric materials under tension have been summarized in this review, the examples that were discussed are typical enough to show the possibilities and impossibilities of NMR for such investigations. It is clear that the combination of stretching (or compression) devices with NMR spectrometers severely limits the type of NMR experiments that can be explored. Nevertheless, enough possibilities remain to study polymers under stress with NMR, as shown for instance by the study of polymer networks. The combination of statistical theoretical techniques and experimental deuterium or wide-line proton NMR has led to a high degree of understanding of the behavior of such systems under stress.

Another field, which has not been reviewed here, but certainly deserves to be considered as a powerful demonstration of the possibilities of NMR, is the study of the viscous behavior of polymer melts under the action of shear.

1 INTRODUCTION

A variety of polysaccharides are known to play essential roles as the structural components in the cell walls of plant and microorganisms, in insect cuticles, as storage polysaccharides, as matrix components in animal fluids and connective tissues, and as molecular signals for biological recognition. These functions are strongly related to their respective secondary structures, taking in the solid, gel, or solution states. Nevertheless, it is not easy to reveal the secondary structures of these polysaccharides either in the solid or in solution, as compared with those of globular proteins or nucleic acids which have been extensively studied by X-ray diffraction or multidimensional NMR spectroscopy. This is mainly because the crystallization of polysaccharides for an X-ray diffraction study is extremely difficult and the number of interresidual nuclear Overhauser enhancements in solution NMR is not sufficient for the purpose of model building. Moreover, it should be emphasized that the secondary structures of polysaccharides are generally very heterogeneous, especially in the gel state in which several different kinds of domain are simultaneously present.

Conformational elucidation by solid state NMR spectroscopy as a means for in situ structural analysis is especially important for a number of polysaccharides, because they are in many instances not soluble in mild solvent systems (such as aqueous solution) and other spectroscopic means for this purpose are virtually unavailable. It should be anticipated that solubilization in either alkaline or DMSO solution can usually be associated with a conformational change. In addition, too much reliance should not be laid on a secondary structure as deduced by fiber X-ray diffraction studies, because any physical treatment to improve the crystallinity (such as thermal treatment) may cause a conformational change. There remains an ambiguity about secondary structure owing to the limited number of diffraction data available. In this respect solid state NMR is invaluable as a complement to fiber X-ray diffraction as well as a means to gain insight into the dynamic aspects of polysaccharides, especially in relation to a study of gel networks.

2 CONFORMATION-DEPENDENT ^{13}C CHEMICAL SHIFTS

We have previously shown that the ^{13}C chemical shifts of a variety of molecular systems, including polypeptides and proteins, carbohydrates and polysaccharides, ionophores, etc., vary by as much as 8 ppm depending on their conformations.^{1,2} In principle, such a conformation-dependent change in polysaccharides is observable either in the solid state or in solution when rapid conformational isomerism about the glycosidic linkages is frozen. However, there are a limited number of examples which exhibit the existence of conformation-dependent ^{13}C chemical shifts: ^{13}C chemical shifts recorded in solution are generally identical, within experimental error, to those observed in the solid state, as in higher molecular weight $(1 \rightarrow 3)\text{-}\beta\text{-D-glucans}$ and $\alpha\text{-cycloamylose}$. The situation arose when rapid rotational motion about the glycosidic linkages was frozen (even in solution) due to the formation of cross-links or to the presence of cyclic structures for the $(1 \rightarrow 3)\text{-}\beta\text{-D-glucans}$ and $\alpha\text{-cycloamylose}$, respectively.

The existence of conformation-dependent ^{13}C chemical shifts, however, is more clearly visualized by an examination of the ^{13}C chemical shifts of solid polysaccharides which have a variety of polymorphs. It is also useful to examine the ^{13}C NMR spectra of crystalline cycloamyloses enclosing a variety of guest molecules, because detailed conformational data for such complexes are available from single crystal X-ray diffraction studies. We previously demonstrated that the C-1 and C-4 ^{13}C chemical shifts of crystalline cycloamyloses enclosing various types of guest molecules could be well related to a set of torsion angles about the glycosidic linkages (ϕ , ψ).³ Later, similar but slightly different relationships^{4,5} were proposed. Therefore, conformational elucidation by means of solid state NMR is feasible on the basis of the concept of conformation-dependent ^{13}C chemical shifts.^{1,2}

3 SECONDARY STRUCTURE OF GEL-FORMING POLYSACCHARIDES

It is well recognized that cross-links of polysaccharide gels are formed via several degrees of molecular association of the ordered polysaccharide chains. It is thus important to obtain the detailed in situ secondary structure of various polymorphs of polysaccharides by solid state NMR as reference data useful for conformational studies of gel samples.

3.1 $(1 \rightarrow 3)\text{-}\beta\text{-D-Glucans}$

As an illustrative example, we first demonstrate comparative ^{13}C NMR studies on linear and branched $(1 \rightarrow 3)\text{-}\beta\text{-D-glucans}$ isolated from bacteria and reserve polysaccharide, and fungi (edible mushrooms), respectively.^{6,7} Curdlan [(1), Figure 1], a bacterial linear $(1 \rightarrow 3)\text{-}\beta\text{-D-glucan}$ from *Alcaligenes faecalis* (Wako Pure Chemicals, Osaka, Japan) is able to form a firm elastic gel when its aqueous suspension is heated at a temperature above 54 °C. On the other hand, several branched glucans such as lentinan (Ajinomoto Co. Japan), schizophyllan (Taito, Japan), etc. (2) from various types of mushrooms are able to form gels of a rather brittle type at higher

Figure 1 Primary structures of a variety of polysaccharides

concentrations (>10%). Such a difference in macroscopic texture of these gel samples is closely related to a different architecture of the network structure between the two types of gels, as will be discussed later in more detail. In fact, rather sharp ¹³C NMR signals (about 40% of the total NMR spectrum) are visible from curdlan gel using conventional liquid state NMR with broadband decoupling.⁸ The C-1 and C-3 ¹³C chemical shifts from the elastic gel were displaced to high frequency by 2.8 and 3.2 ppm, respectively, as compared with those of a lower molecular weight glucan with a random coil conformation. As pointed out in the previous section, such a conformation-dependent ¹³C chemical shift of (1 → 3)-β-D-glucans arises from the fact that the rotational motions of the polysaccharide backbone about the glycosidic linkages are frozen due to the formation of an ordered helical conformation. The polysaccharide chain in this case must be a *single* helical species in spite of the existence of a triple helical model, based on fiber X-ray diffraction studies,^{9,10} because the molecular chain is found to be rather flexible, as demonstrated by relaxation parameters such as the spin–lattice relaxation times and the NOE.⁶ In contrast, all of the ¹³C NMR signals of the branched glucans were found to be completely suppressed in the gel state as recorded on a traditional solution state NMR spectrometer.¹¹ This finding implies that the molecular conformations of these two types of polysaccharides are different from each other. It is essential for this reason to examine the solid state ¹³C NMR spectra of various types of polymorphs in (1 → 3)-β-D-glucans for use as reference data.

Figure 2 illustrates the ¹³C NMR spectrum of a hydrated sample of curdlan (b) obtained by placing it in a desiccator at 96% relative humidity for 8 h compared with that of the anhydrous powder as received from the manufacturer (a)¹² and annealed curdlan¹³ prepared by heating an aqueous suspension at 150 °C followed by slow cooling (c). It is noteworthy

Figure 2 ¹³C CP MAS NMR spectra of curdlan in the solid state: (a) anhydrous; (b) hydrated; and (c) annealed¹²

that the ¹³C NMR linewidths of the hydrated sample are considerably narrowed in comparison to those of the anhydrous sample and are comparable to those of the annealed curdlan [Figure 2(c)]. The C-3 ¹³C chemical shift of curdlan hydrate is displaced to low frequency by 2.5 ppm with respect to that of the anhydrous state. Distinction between the hydrated and annealed curdlan is straightforward by means of the C-5 chemical shifts (75.8 ppm and 77.5 ppm for the former and latter, respectively) and the peak separation between the C-5 and C-2 signals (2.0 and 3.2 ppm, respectively). Lyophilized curdlan from DMSO solution gave rise to narrower spectra but the peak positions were exactly the same as those for the anhydrous sample.¹⁴ Annealed curdlan may be related straightforwardly to the triple-helix form on the basis of its powder X-ray diffraction by reference to previous fiber diffraction data.^{9,10}

Hydrated curdlan gave rise to ¹³C NMR signals which were identical to those observed in the gel state. Hence, this form was ascribed to the flexible single helix already mentioned. Consistent with this view, a recent fiber X-ray diffraction¹⁵ study showed the presence of a 6/1 single helix conformation for the curdlan gel prepared by heating an aqueous suspension at 70 °C for 10 min, although Fulton and Atkins previously ascribed a similar diffraction pattern to a 7/1 triple helix conformation.¹⁶ It is surprising that the C-1 and C-3 chemical shifts of the single helical curdlan hydrate are very similar to those of the triple helical annealed curdlan, although distinction between the two forms is possible from the C-2 and C-5 peaks. This is because the two pairs of the torsion angles about the glycosidic linkages (ϕ , ψ) are very similar, as revealed by X-ray diffraction studies.^{10,15} The anhydrous form, on the other hand, is ascribed to a single-chain form whose torsion angles vary to some extent from those of the single helix form owing to loss of hydrated water molecules (which are essential for stability in the single helix conformation). In a similar manner, DMSO molecules in the single-chain form are complexed with the polysaccharide chains (ca. 0.5 DMSO molecules per residue)¹⁴ and may play an important role for the conformational stabilization, although they are readily replaced by water molecules on hydration

to yield the single helix form.^{12,14} This situation is very similar to the case of DMSO molecules complexed with V-amylose, which are very easily replaced by water molecules by hydration, leading to the conversion to the B- form, as will be described later.

Linear (1 → 3)- β -D-glucans of low molecular weight oligomers such as laminariheptaose and acid-degraded curdlan with a degree of polymerisation (*DP*) of 14 can adopt neither the single helix nor triple helix form, as judged from the characteristic ¹³C signals.^{12,13,17} Interestingly, glucans of either short-chain (*DP* < 14) or longer-chain species are incapable of forming triple helices by lyophilization from aqueous solution. Laminaran from *Laminaria* species (*DP* 39) turned out to be able to exist in the triple helix form by lyophilization from aqueous solution, although this polysaccharide adopts a random coil form in aqueous solution.¹³ In contrast, triple helix conformations were achieved when high molecular weight branched (1 → 3)- β -D-glucans such as schizophyllan or HA- β -glucan were lyophilized from their aqueous solution, although the single-chain form was available from an aqueous solution of lentinan.¹⁷ It is now clear that the obvious preponderance of the single helix conformation for the linear (1 → 3)- β -D-glucans of high molecular weight arises mainly from insufficient hydration. Once this molecule is completely dissolved in an aqueous solution at a temperature above 150 °C, it is able to refold to yield the triple helical conformation when cooled slowly to ambient temperature.¹³ It is thus expected that such a conversion is inefficient when heated samples are cooled rapidly (at most 50%).¹³ It is noteworthy that conversion of the single helix to the triple helix by annealing at 150 °C is accompanied by fragmentation of the polymer chain due to thermal degradation from an initial *DP* of 3930 to a final *DP* of 110.¹⁸ Such an annealing is not necessary in the case of the branched glucans, because these molecules are well hydrated in aqueous media at ambient temperature. It appears that rather weak intermolecular association of the branched glucan (as compared with that of the linear glucan) arises from the presence of a pendant glucose moiety (Figure 1) for every two or three glucose residues. This is the reason why the branched (1 → 3)- β -D-glucans and laminaran have a preponderance of the triple helix over the single helix conformations.

In general, several types of polysaccharides including (1 → 3)- β -D-glucans can acquire the double or triple stranded form as the most energetically stable, as expected from a molecular mechanics calculation.¹⁹ Nevertheless, any given polysaccharide sample does not always take the energetically most stable conformation, because of different sample histories. Distinction between the single and multiple helical chains, however, is not always straightforward to obtain by X-ray diffraction, because distinguishing multiple stranded coaxial helices and nested single helices is one of the most difficult problems encountered in interpreting fiber diffraction data.²⁰ It should be emphasized that this problem is readily solved by examination of the conversion diagram of these polysaccharides after a series of physical treatments, as summarized in Figure 3. The present approach can be further extended to any types of polysaccharide. In fact, a very similar conversion diagram was recently obtained for (1 → 3)- β -D-xylan (3), which is also found to acquire the three above-mentioned types of conformation, as may be expected from its structural similarity with (1 → 3)- β -D-glucans.²¹ The

Figure 3 Conversion diagram for (1 → 3)- β -D-glucans by various physical treatments (based on Saitô et al.^{12,13})

triple helical conformation was initially proposed for (1 → 3)- β -D-xylan²² and then adopted for (1 → 3)- β -D-glucan, because the C-6 hydroxymethyl group of the latter is located outside the helical chains. It turned out that the triple helix conformation of the former is more stable than that of the latter because of the greater hydrophobic character in the polymer chain and it cannot be readily converted to the single chain form even if dissolved in DMSO. This type of conversion was made possible by dissolution of the sample in aqueous zinc chloride solution in place of the more common DMSO solution.²¹

3.2 Amylose and Starch

Amylose (4) has a common feature with (1 → 3)- β -D-glucans as viewed from the presence of the single helical conformation, which is stabilized by DMSO molecules, and also from its gel-forming ability. Amylose and starch are known to have the following four kinds of polymorphs: V-, A-, B-, and C-forms.^{23,24} The V form exists as a complex with a variety of small organic molecules and has a left-handed single helical conformation. The A- and B-forms are found in cereal and tuber starches, respectively, and can be distinguished by the splittings of the C-1 peaks as triplet and doublet peaks, respectively.^{25–27} In contrast, V-amylose gives rise to single lines.²⁸ The C-4 peak of V-amylose is particularly displaced to high frequency by ca. 4–5 ppm from that of the B form. These amylose polymorphs can also be mutually interconverted by a series of physical treatments in a similar manner to (1 → 3)- β -D-glucan, as demonstrated for amylose of low molecular weight (*DP* 17, Figure 4).²⁹ Obviously, anhydrous amylose lyophilized from a DMSO solution [Figure 4(b)] gave rise to a spectral pattern of the V form. The anhydrous powder as received, however, has an amorphous structure distorted from the B form, as judged from the broad envelope of the ¹³C NMR signal in the C-1 region and the absence of the C-4 peak at 81 ppm [Figure 4(a)]. Furthermore, hydration of the anhydrous powder or V-amylose resulted in conversion to the B-amylose as judged from the ¹³C NMR spectra [Figure 4(c)]. It is interesting that such conversion occurs efficiently for amylose of either low (*DP* 17) or high (*DP* 1000) molecular weight but was incomplete for amylose of intermediate molecular weight (*DP* 100).²⁹

The secondary structure of the B form was initially considered to be the single helical conformation,³⁰ since the conversion of the V- to the B-form amylose takes place on humidification.³¹ Later, however, the structure was refined as

Figure 4 ^{13}C CP MAS NMR spectra of low molecular weight amylose (DP 17): (a) anhydrous powder; (b) anhydrous lyophilized sample from DMSO solution; (c) hydrated amylose powder; and (d) hydrated iodine complex²⁹

a right-handed double helix in an antiparallel fashion.³² The handedness of the double helix form, however, was recently revised as a left-handed double helix.³³ Nevertheless, it is hardly likely that simple humidification of amylose by placing it in a desiccator at a relative humidity of 96% causes such a drastic conformational change. In this connection, it is crucially important to clarify whether the secondary structure of B-amylose is a left-handed single helix as suggested from solid state NMR or a left-handed double helix as suggested from fiber X-ray diffraction study.

It was expected that ^2H NMR spectra of $^2\text{H}_2\text{O}$ or $\text{DMSO-}d_6$ complexed to amylose by forming the B- or V-form would be split into a doublet pattern, with the separation of peaks being about 100–200 kHz and 40 kHz (with C_3 rotation of the methyl group), respectively, if they are tightly bound to the polymer chains (static). It emerged, however, that only a singlet was visible as a result of rapid isotropic averaging of the quadrupole interaction in the solid state, with correlation times on the order of 10^{-6} s. The correlation times of isotropic tumbling of $^2\text{H}_2\text{O}$ and $\text{DMSO-}d_6$ as estimated from ^2H spin–lattice relaxation times are found to be in the vicinity of the T_1 minimum and on the high-temperature side of the T_1 minimum, respectively.²⁹

4 DYNAMIC ASPECTS OF POLYSACCHARIDE GELS

Network structures of gel samples should be highly heterogeneous from the conformational and dynamic point of

view. Any single NMR measurement, however, does not give rise to such information, because the correlation times of the molecular motions may be broadly distributed from the liquid- to solid-like domains. We have already demonstrated that ^{13}C NMR signals from the liquid-like domains are easily visible with a conventional solution state spectrometer but those of the solid-like domains are not.^{5,6} It is therefore necessary to record NMR signals from these solid-like domains in order to gain some insight into the gel structure and dynamics. It is accordingly a major advantage of the NMR approach that it is able to select a particular domain from a variety of motionally different domains.

We have recorded ^{13}C NMR spectra of curdlan gels (Figure 5) by various methods including broadband decoupling for the liquid-like domain as discussed above (b), high-power dipolar decoupling with magic angle spinning (MAS) for intermediate domains between the liquid- and solid-like domains (c), and cross-polarization magic angle spinning (CP MAS) for the solid-like domains (d), and have compared these with the ^{13}C NMR spectrum of hydrated curdlan (a).³⁴ Such comparison indicated that the single helix form is dominant for all of the motionally different domains of an elastic curdlan gel, although a low intensity peak arising from the contribution from the triple helix is visible in the solid-like domains as shown by the arrowed peak in the CP MAS NMR spectrum. It is worthwhile to relate here the present view of the gel structure with the data for gel strength as a function of heating temperature:³⁵ the gel strength is almost the same at temperatures between 60–80 °C (low-set gel) and thereafter increases with heating temperature together with the development of turbidity and shrinkage of the gel (high-set gel). The first step of gelation thus corresponds to the formation of pseudo cross-links by hydrophobic association of

Figure 5 ^{13}C NMR spectra of curdlan gel (b–d) and curdlan hydrate (a) recorded by various types of NMR measurements: (a) and (d) by CP MAS; (b) by broadband decoupling; and (c) by MAS experiments³⁴

the single helical chain. The increased gel strength in the high-set gel is well explained in terms of an increased proportion of the triple helical conformation.^{5,6}

On the other hand, we found that ¹³C NMR spectra of branched glucans such as lentinan, schizophyllan, and HA- β -glucan exhibited characteristic peaks of the triple helix conformation.³⁴ As pointed out, such a preponderance of the triple helix forms resulted in the complete absence of the peaks from the liquid-like domains.^{5,6} In this connection, Yanaki and co-workers³⁶ showed that the triple helical chain of (1 $\rightarrow$ 3)- β -D-glucans is stiffer than that of native collagen, as manifested from the measurements of persistent chain length for schizophyllan (2000 ± 300 Å). This means that the resulting slow tumbling motion of the stiff rod-like triple helices is not sufficient to average out the dipolar or chemical shift anisotropy interactions in the gel state. Thus, it follows that the major gelation mechanism for the branched (1 $\rightarrow$ 3)- β -D-glucans proceeds from partial association of the triple helical chains. It appears that the absence of the flexible molecular chain is consistent with the property of a brittle gel. Here we point out that the linear and branched (1 $\rightarrow$ 3)- β -D-glucans so far discussed are involved in a variety of host-defence biological responses such as antitumor activity, activation of the coagulation system of horseshoe crab amebocyte lysate (LAL), etc. It is interesting that such biological response is initiated by recognition of the molecular chains of the single helical conformations.^{18,37,38}

Gidley³⁹ showed that amylose gel exhibits two kinds of ¹³C NMR signals: B type signals from motionally restricted regions as recorded by the CP MAS technique and signals identical to those found in aqueous solution. Obviously the latter signals can be ascribed to the presence of a mobile region (liquid-like domain) in the network whose conformation is random coil. The former peaks are naturally ascribed to the solid-like domain with cross-links, either consisting of double helical junction zones,³⁹ or aggregated regions of the single helical chains²⁹ as discussed in the previous section. To date, two different views have been presented for the gelation mechanism of amylose: Miles et al.⁴⁰ have suggested that gels are formed upon cooling molecularly entangled solutions as a result of phase separation of the polymer-rich phase, whereas Wu and Sarko³³ proposed that gelation occurs through cross-linking by double helical junction zones. Recently, we measured the ¹³C spin-lattice relaxation times of the liquid- and solid-like domains of starch gel by means of dipolar decoupled single pulse MAS and CP MAS, respectively.⁴¹ It turned out that the T_1 of the C-6 carbon is 0.16 s and 2.1 s for the former and latter, respectively. It appears that such a long T_1 for the latter as compared with that of other types of swollen gels (<0.5 s) arises mainly from motionally restricted crystalline portions consisting of aggregated molecular species such as single helical chains. In any case, it is crucially important to distinguish single helical chains from double helical chains by means of solid state NMR spectroscopy.

5 CONCLUDING REMARKS

It has been demonstrated that the solid state NMR approach is a very powerful means of clarifying conformational features of a variety of polysaccharides in an empirical manner based on the concept of the conformation-dependent displacements

of ¹³C chemical shifts. Careful examination of an NMR-based conversion diagram by a series of physical treatments has proved to be a very useful means for the distinction of single-chain/multiple helices. The application of a modern methodology is urgently required to determine the secondary structure in a nonempirical manner, such as rotational echo double resonance or rotational resonance as currently being applied to a variety of peptides or proteins in the solid state.

1 INTRODUCTION

Complex oligosaccharides and polysaccharides are composed of a wide variety of different monosaccharides in different linkages. They are not involved as energy sources in metabolism but should be considered rather as 'informational macromolecules' encoding information which is generally important in intercellular communication. The information which they store is decoded by interaction with specific binding proteins known as lectins.¹ The cell surface oligosaccharides of membrane glycoproteins and glycolipids have been implicated in such important biological functions as inflammation² and cellular differentiation.³ The cell surface polysaccharides of bacteria, including lipopolysaccharides, capsular polysaccharides, and other cell wall polysaccharides are implicated in bacterial adhesion and coaggregation.^{4,5} Two different aspects of the structure are important to an understanding of the biology of these interactions. First, one must determine the covalent chemical structure of complex oligosaccharides and polysaccharides including the absolute configuration of the constituent monosaccharides. Secondly, one must also determine their three-dimensional folding and their conformation. If they do not adopt a single conformation but rather exist in multiple conformations which exchange, then one must also determine the dynamics of the conformational exchange. This knowledge will make a major contribution to our understanding the interactions of complex oligosaccharides with lectins. High-resolution NMR spectroscopy has been important in all three facets of the structure of complex oligosaccharides and polysaccharides.

2 COVALENT STRUCTURE DETERMINATION

Determination of the covalent structure of a complex oligosaccharide or polysaccharide is not so simple as determination of a peptide sequence or of a nucleotide sequence. With the possibility of two sugar ring forms (furanoside or pyranoside) and of two anomeric forms (α and β) as well as multiple linkage positions, much more detailed information is required for a description of the structure of a complex oligosaccharide which often includes branching. At present

there is no single established method for structure determination and many different methods involving enzymatic digestion, chemical degradation, and methylation analysis are used for various problems. The catalog of available *endo*- and *exo*-glycosidases is inadequate and the outcome of chemical reactions involving sugars is notoriously unpredictable. These facts contribute to the attractiveness of instrumental methods such as mass spectrometry and NMR spectroscopy which require minimal chemistry.

2.1 Proton NMR Spectroscopy

The first major contribution of high-resolution ^1H NMR spectroscopy to this problem was the structural reporter group method which became useful with the introduction of high-field superconducting spectrometers operating at 360 MHz. An oligosaccharide or polysaccharide in the quantity range of 100 nmol to 1 μmol is dissolved in D_2O and a ^1H spectrum is recorded with chemical shifts referred to DSS.^{6,7} In this method, which was first used in glycopeptides and was later extended to glycolipids in DMSO solution, certain well-resolved resonances can often be recognized in one-dimensional spectra. For example the anomeric region at ca. 4.4–5.4 ppm usually contains resonances of anomeric protons most of which are isolated (see *Carbohydrates and Glycoconjugates*). Accurately measured values of the chemical shift can be combined with the multiplet splitting to characterize the oligosaccharide or polysaccharide. Other structural reporter resonances which contribute to the fingerprint include methyl doublets near 1.3–1.5 ppm typical of 6-deoxyhexoses and methyl singlets around 2.0 ppm characteristic of *N*- or *O*-acetyl methyl groups. Methylene resonances of 3-deoxy sugars can be found between 1.8 and 2.3 ppm. But many overlapping resonances of the methine protons between 3.5 and 4.0 ppm are unresolved and contribute minimal information. The chemical shifts and multiplet structures of the isolated structural reporter resonances can be used to characterize the oligosaccharide or polysaccharide, since no two distinct structures have ever been found to have the same NMR spectrum.

Although the structural reporter method has been used primarily for *N*-linked glycopeptides and glycolipids, it can be used on any oligosaccharide or polysaccharide for which a reference library of closely related structures is available (see *Carbohydrates and Glycoconjugates*). The method has also been used extensively for the oligosaccharide alditols isolated from the alkaline borohydride degradation of mucin glycoproteins.^{8–10} In polysaccharides with a repeating subunit, only the structural reporter resonances of the repeat unit are observed and the spectrum resembles that of an oligosaccharide without a reducing terminal. The method works well in any system of closely related bacterial polysaccharides.¹¹ Although the structural reporter method has been generally associated with ^1H NMR spectroscopy, a very similar approach has been used in the ^{13}C NMR of bacterial polysaccharides as will be described below. The structural reporter method for ^1H spectra is fast (~ 30 min) requiring less spectrometer time than other NMR methods and is comparatively sensitive yielding at least some information on samples as small as 20–100 nmol.

A complete assignment of all the proton signals is more difficult, but it provides much more information

on the structure of a polysaccharide for which there are no available spectra for closely similar compounds. A complete assignment of the ^1H spectrum can in principle be established by spin correlation since each sugar ring forms a chain of scalar coupled spins. While correlation by scalar coupling was originally done by spin decoupling, usually by difference methods, two-dimensional methods such as COSY are generally preferred for modern instrumentation. The experiment is usually performed in a phase-sensitive mode with a double quantum filter.^{11,12} Spin correlation is started at the anomeric proton resonance or at some other structural reporter resonance such as a methyl doublet of a 6-deoxyhexose. Correlation through the entire spin system by COSY can be augmented by 2D HOHAHA or TOCSY which is especially valuable for resonances which are close in chemical shift, giving rise to COSY cross peaks close to the diagonal.¹³ From these 2D COSY and TOCSY spectra, one can extract the homonuclear coupling constants which are very useful in assigning the stereochemistry of the sugar pyranoside residue. Two vicinally coupled protons which are axial make a dihedral angle of 180° implying a large coupling constant which is observed in practice to range from 7–11 Hz, whereas any coupling involving equatorial protons exhibits a small *gauche* coupling constant ranging in practice from 0.5–3 Hz (see *Vicinal Coupling Constants and Conformation of Biomolecules*). Hence these data reveal whether substituents are axial or equatorial, providing the anomeric configuration of the glycosidic linkage as well as the identity of the sugar residue. The identities of the monosaccharides are then to be confirmed by carbohydrate analysis by a method such as HPLC.

Two common difficulties arise which may prevent the above scheme from providing a successful assignment of the ^1H spectrum. The first problem is strong coupling which is all too common in the crowded 3.4–4.4 ppm region of the carbohydrate spectrum. It arises when the chemical shifts of two resonances which are coupled are separated by an amount which is not large compared with the coupling constant. Homonuclear two-dimensional TOCSY or HOHAHA spectroscopy can be used to obtain cross peaks which are well removed from the diagonal in many cases. But if the difference in chemical shift is less than twice the coupling constant, the multiplet shape cannot be extracted interfering with the assignment of stereochemistry by homonuclear coupling, $^3J(\text{H,H})$. In this case, heteronuclear NMR methods involving ^{13}C resolution are required, as will be discussed below. A second problem in spin correlation about the ring arises for very small values of $^3J(\text{H,H})$ associated with some *gauche* protons.

NOESY correlations can often be used to correlate such *gauche* protons since they are close in space. A hybrid homonuclear method combining TOCSY with ROESY or NOESY may be useful in such cases and long-range heteronuclear coupling correlation can also be useful as will be described below (see *Carbohydrates and Glycoconjugates*).

Although the scheme outlined above for spin correlation can be used to assign all proton resonances in a ring and to identify the sugar residues and their anomeric configuration, it does not provide the sequence of residues or their linkage and branching. For this purpose, homonuclear spin correlation is not informative and correlation through space by NOESY can be employed. The anomeric proton of one residue is often

close to the aglycone proton directly across the glycosidic linkage, giving rise to NOESY cross peaks which identify the linkage.^{13,14} Unfortunately this proximity depends on the conformation of the glycosidic linkage and many exceptions are observed in which a large NOE is seen between the anomeric proton resonance and that of the proton adjacent to the linkage position. This situation arises most often when the adjacent proton is equatorial.^{11,13} Although the NOESY data can be useful for the assignment of oligosaccharide sequences, the information on the linkage position is not definitive unless the conformation is known, which is usually not the case for a completely new polysaccharide of unknown structure. Thus the linkage position must be confirmed by some other type of data, such as methylation analysis or long-range heteronuclear correlation to be described below.

Observation of NOESY in oligosaccharides and polysaccharides is complicated by difficulties arising from a dependence on the rotational correlation time. NOE is positive for small molecules and negative for larger ones such as proteins and DNA duplexes.¹⁵ (See *Nuclear Overhauser Effect*.) For intermediate sized molecules having a rotational correlation time τ_c approximately equal to the reciprocal of the spectrometer frequency ω , the NOE disappears altogether. This is approximately the case for a tetrasaccharide at 500 MHz. One solution to this problem is to change the viscosity of the solution, and thus the τ_c , by changing the sample probe temperature¹⁶ or the viscosity of the solvent by the addition of a viscous cosolvent such as DMSO.^{17,18} If it is not desirable to alter the solvent conditions, one can resort to NOE in the rotating frame for which NOEs are positive for all rotational correlation times (see *ROESY* and *Carbohydrates and Glycoconjugates*.) One difficulty with this experiment, which is known as ROESY, is that one must be careful to account for magnetization transfer by the HOHAHA mechanism which leads to cross peaks of the opposite sign and which may cancel ROESY peaks.

The observation of a NOE in polysaccharides is usually straightforward since it is commonly large and negative. Wide variations in flexibility are observed among polysaccharides depending strongly on the linkages. Thus wide variations of linewidth are observed, but generally the NOE is negative.¹¹ The dynamics of the internal motion in polysaccharides is a complex topic which will be addressed below.

2.2 Carbon-13 NMR Spectroscopy

The ^{13}C spectra of carbohydrates generally show much better chemical shift dispersion than do the ^1H spectra. In D_2O solution referenced to DSS, the anomeric signals are dispersed between 95 and 110 ppm and methyl carbon resonances are observed at 15–25 ppm. Since the signals corresponding to the methine carbon atoms of the sugar ring are spread over a much wider spectral region (between 55 and 85 ppm) than are the corresponding signals in the ^1H spectrum, there is only a moderate amount of overlap of the signals even at the low fields typical of iron core magnet NMR spectrometers (20–25 MHz carbon ^{13}C frequency). With the introduction of Fourier transform ^{13}C spectroscopy in the 1970s, the spectra of many carbohydrates were recorded, revealing both the promise and some of the difficulties with this type of spectroscopy. A major problem arises from the low sensitivity associated with the direct observation of ^{13}C in natural abundance, especially

with low magnetic field strength spectrometers. Although the requirement for sample sizes of 20–50 μmol severely limited applications to oligosaccharides from eukaryotic glycopeptides and glycolipids, bacterial polysaccharides are often available in such quantities and spectra were reported for a number of bacterial polysaccharides such as the *O*-antigen chains of lipopolysaccharides (LPS), capsular polysaccharides, and other bacterial cell wall polysaccharides.^{19–21} A second problem with these early studies of ^{13}C NMR spectra of carbohydrates was the lack of a simple method for the rigorous assignment of ^{13}C signals analogous to the $^3J(\text{H},\text{H})$ correlation method described above for the assignment of ^1H spectra. In the absence of a correlation method, the only data upon which to base resonance assignments were ^{13}C chemical shifts and extensive sets of rules for 'glycosylation shifts' were developed.^{22,23} Recently more sophisticated computer-based schemes for this type of correlation have been developed for complex oligosaccharides.^{24–26} Although the large chemical shift dispersion of ^{13}C spectra leads to well-resolved spectra, the large effects complicate any rational scheme for assignment based on regular differences in chemical shifts. This situation has led to many revisions of the spectral assignments of the ^{13}C spectra of complex carbohydrates as more rigorous correlation-based methods for assignment were introduced. These methods include specific ^{13}C incorporation by chemical synthesis,²⁷ DEPT methods which count the protons bonded to a particular carbon atom,²⁸ or comparison of chemical shifts in D_2O and H_2O solution (DIS).²⁹ In spite of the difficulties in obtaining reliable ^{13}C resonance assignments in these early ^{13}C studies, the data proved to be immensely useful in studies of bacterial polysaccharide structure.^{19,20}

Major advances in ^{13}C NMR spectroscopy of polysaccharides have resulted from the more common use of correlation methods which follow chemical bonds. Rigorous assignment of the ^{13}C spectrum can be derived from the ^1H assignment by one-bond C–H coupling correlation. While such a correlation is not very practical for ^{13}C detection in macromolecules, the recent introduction of inverse detection or ^1H -detected ^{13}C spectroscopy has greatly increased the utility of this approach. Not only is the sensitivity of ^1H -detected ^{13}C spectra greatly improved, but it also gives the ^1H spectrum the higher resolution of the detected dimension where it is most needed. In a convenient implementation called HMQC³⁰ the rather crowded ^1H spectrum is resolved in the F_1 dimension by the excellent dispersion of the ^{13}C dimension. This spreads out the resonances that would otherwise overlap in the ^1H spectrum and also provides a scheme for the assignment of the ^{13}C resonances once a rigorous assignment of the ^1H spectrum is derived from homonuclear spin correlation as described above.³¹ Another advantage of HMQC arises in the case of strongly coupled ^1H resonances, which are often resolved by the difference in ^{13}C chemical shift. The large value of $^1J(\text{C},\text{H})$ ($\sim 140\text{ Hz}$) removes the strong coupling for natural abundance samples in which there is only one ^{13}C atom in the average sugar ring.¹¹ In the absence of strong coupling, the correct homonuclear multiplet shape can be deduced as required for the assignment of the stereochemistry of the pyranoside ring and identification of the sugar. With hybrid methods such as coupled HMQC–COSY, one can assign the correct multiplet shape and chemical shift even in cases for which the ^1H resonances exactly overlap.³² The combination of ^1H homonuclear correlation and ^1H -detected ^{13}C correlation enables a complete

assignment of both spectra for complex carbohydrates which are available in quantities of about 1 μmol . This is reasonable for bacterial polysaccharides, but may not be suitable for glycopeptides or glycolipids from eukaryotes which are often not available in such large quantities.

Another important extension of these heteronuclear methods is long-range correlation of ^1H with ^{13}C over two and three bonds by the method popularly known as HMBC.³³ The pulse sequence is similar to that used for HMQC but it involves longer delays to allow antiphase magnetization to develop over the smaller coupling. In this experiment, there is a reduction in sensitivity due to the long delays (30–50 ms) which are required and if T_2 is not much longer than the delays, substantial signal is lost. Particularly for polysaccharide samples with wide lines, this experiment is less sensitive than HMQC and can require as much as 10 μmol of sample depending on the linewidth. HMBC spectra provide valuable confirmation of ^1H and ^{13}C resonance assignments through correlation within the sugar ring, and also complete assignments for cases in which vicinal homonuclear coupling constants are too small to provide correlation.¹¹ But the main function of HMBC spectra is correlation across the glycosidic linkage.³¹ This allows assignment of the glycosidic linkage in a rigorous way which follows the chemical bonds. This method has found a number of recent applications for determining glycosidic linkages in bacterial polysaccharides.¹¹ In favorable cases, this information can take the place of data from methylation analysis and a complete structure of a polysaccharide can be determined essentially by NMR methods with very little ancillary data.

3 CONFORMATION AND DYNAMICS

The question of the three-dimensional conformation of complex oligosaccharides and polysaccharides is distinct from the primary or covalent structure. A truly detailed understanding of the conformation and dynamics requires contributions from a number of techniques, but at the present time data from NMR spectroscopy have made the most significant contributions to the solution of this problem. Computer molecular modeling is generally essential to the satisfactory interpretation of the experimental NMR data.³⁴ It seems likely that contributions from other experimental biophysical methods such as X-ray crystallography and fluorescence spectroscopy can be expected to increase as the importance of oligosaccharide–lectin interactions becomes more apparent.³⁵

An early contribution of NMR data to oligosaccharide conformation was the homonuclear $^3J(\text{H},\text{H})$ values which are especially useful for determining the puckering of the pyranoside rings of sugars. Since the six-membered pyranoside rings generally assume defined chairs, their $^3J(\text{H},\text{H})$ values are either large (7–11 Hz) for coupling between axial protons or small (0–3 Hz) for coupling involving equatorial protons, as is described above in connection with the assignment of ring stereochemistry. For furanosides, the pucker is much more complicated, with the five-membered rings adopting envelope conformations in rapid exchange. Measurements of $^3J(\text{H},\text{H})$ for furanosides have been useful in determining the relative contributions from the various envelope conformations which are important in DNA and RNA conformation.³⁶

(See *Vicinal Coupling Constants and Conformation of Biomolecules*.) A combination of empirical and ab initio calculations has been used to model the furanoside rings and to fit the $^3J(\text{H,H})$ data to the model.

For oligosaccharides composed of relatively rigid pyranoside rings, the glycosidic dihedral angles describe the conformation and dynamics of the polysaccharide.³⁷ Homonuclear coupling data are uninformative regarding the relative conformation of the rings with respect to each other and much more information on oligosaccharide and polysaccharide conformation has been derived from ^1H NOE data which report on distances through space.¹⁵ (See *Nuclear Overhauser Effect*.) The strategy is similar to that used in the determination of protein structure in solution by NMR methods which relies heavily on computer modeling methods for an interpretation of the NMR data (See *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). The earliest studies of oligosaccharide conformation were performed on chemically synthesized models of blood group oligosaccharides in which steady-state NOEs were interpreted qualitatively.³⁸ Models were built with a simple empirical energy function and the NOE data were interpreted qualitatively to confirm these models. This method has also been used in bacterial polysaccharides.^{39,40}

A more quantitative method for incorporating the NOE data into molecular modeling schemes follows methods often used in the interpretation of NMR data of proteins in which experimental distance constraints are derived from the NOE data. The distance constraints, which are most commonly derived from the 'isolated spin pair approximation', are treated as pseudo energy terms in the modeling to force a conformation which is consistent with the experimental NOE data (see *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). Choe et al.⁴¹ have used NOE constraints to study the core oligosaccharide of the glycosamino glycans and Scarsdale et al.⁴² have described an application to gangliosides. Homans and Forster⁴³ have also outlined a detailed method for restrained molecular dynamics for oligosaccharides.

A slightly different approach to the quantitative evaluation of NOE data for modeling of oligosaccharides is spin matrix analysis. In this method a molecular model is built and interactions among all the ^1H spins are treated to include three spin effects and spin diffusion (see *Protein Structures: Relaxation Matrix Refinement*). The model is then adjusted to determine whether any conformation can be found for which all the simulated NOE data agree with experiment. This method was first introduced by Brisson and Carver⁴⁴ for steady-state NOE in glycopeptides. The matrix method for oligosaccharides was later extended to transient two-dimensional NOESY data which are technically more convenient.⁴⁵ The spin matrix method has been adapted to include quantitative interpretation of rotating frame or ROESY data.⁴⁶

An inherent problem with both methods outlined above for the quantitative interpretation of NOE data for oligosaccharides is that they ignore internal motion. The matrix method begins with the assumption of a simple isotropically rotating rigid model and the restrained molecular modeling methods are generally assumed to converge to a single conformation. Careful analysis of the results of either method can be used to

test for consistency of a single rigid model with the experimental data, but it is difficult to incorporate internal motion into a quantitative NOESY calculation. The question of the flexibility of complex oligosaccharides is important and remains somewhat controversial.^{47,48} Certainly, the relatively narrow lines observed in NMR spectra of polysaccharides (2–15 Hz) having molecular weights as high as 100 kDa suggest that there must be some type of flexibility. One possible interpretation is that certain types of oligosaccharides, such as the blood group epitopes, do assume relatively rigid conformations, while other sugar linkages are flexible, providing structural 'hinges'.^{34,48}

One approach to the interpretation of NOE in the presence of internal motion is to assume that the molecular modeling results are correct, assign statistical weights to the minimum energy conformations, and then calculate average NOE. Under the assumption that the rate of conformational exchange is fast compared with T_1 but slow compared with the overall τ_c of the oligosaccharide, one may average the values of the spin matrix elements and then solve the problem.^{45,48} Unfortunately it is not known whether this assumption about the kinetics of conformational exchange is correct.

The uncertainty about the details of the conformational dynamics of polysaccharides suggests that additional types of experimental information are needed. The interpretation of NOESY data for a system with internal motion can be quite complex since motion can modulate not only the orientation of ^1H – ^1H vectors but also the distances between protons. It has been recognized for many years that heteronuclear coupling $^3J(\text{C,H})$ values could be used to correlate with dihedral angles (see *Vicinal Coupling Constants and Conformation of Biomolecules*). Interpretation of coupling data such as $^3J(\text{C,H})$ in an oligosaccharide with internal motion is much simpler than NOE since the motion is almost certainly fast compared with the timescale of the interaction (ms). But it has proven to be technically very difficult to measure these coupling constants for macromolecules with ^{13}C in natural abundance. Data were first reported from 1D ^{13}C spectra and ^1H spectra of oligosaccharides synthesized with specific ^{13}C enrichment.²⁷ More recently, long-range heteronuclear coupling constants have been measured in natural abundance by ^{13}C -detected ^1H spin echo methods.⁴⁹ But the low sensitivity of ^{13}C -detected methods presents a serious limitation and this method requires a resolved ^1H spectrum which is a rarity in complex carbohydrates. The improved sensitivity of ^1H detection, which has been described above for long-range ^{13}C – ^1H correlation, provides a method for encoding values of $^3J(\text{C,H})$.⁵⁰ Several one-dimensional versions of ^1H -detected $^3J(\text{C,H})$ have been demonstrated in disaccharides and trisaccharides by Poppe and van Halbeek.⁵¹ In spite of the improved sensitivity, cancellation of the antiphase components of heteronuclear doublets hampers accurate measurements for macromolecules. When the linewidths are comparable to the values of the coupling constants (1–8 Hz), the latter cannot be accurately measured due to antiphase cancellation. In the ECOSY method of Montelione et al.,⁵² large one-bond coupling to resolve the long-range coupling removes the problem of overlap making it possible to measure accurately coupling constants much smaller than the linewidth.⁵³ (See *Coupling Constants Determined by ECOSY*.) This approach has been used in carbohydrates in natural abundance with ^{13}C selective filters,⁵⁴ and in polysaccharides with uniform ^{13}C enrichment.⁵⁵

The question of internal motion in complex polysaccharides can also be addressed by spin relaxation methods in which $J(\omega)$, the spectral density, is sampled at a number of different frequencies to measure the different types of motion which contribute to nuclear relaxation. Measurements of different relaxation rates, T_1 , T_2 , $T_{1\rho}$, and NOE of ^{15}N or ^{13}C can be combined in order to provide this information.

1 INTRODUCTION

The structural investigation of peptides, polypeptides, proteins, and other biopolymers in the solid state is being pursued increasingly by means of high-resolution solid state NMR.^{1–8} Most of the biopolymers considered here consist of repeating sequences of peptide bonds with 20 different types of substituent at the α carbon. The secondary structures of these biopolymers are classified as α -helix, β -sheet, ω -helix, and so on, by means of a set of dihedral angles (ϕ , ψ).

In the solution state, the NMR chemical shifts of biopolymers with internal rotations are often the averaged values for all internal rotations because of rapid interconversion by rotation about peptide bonds. In the solid state, however, chemical shifts are often characteristic of specific conformations because of highly restricted rotation about the peptide bonds. The NMR chemical shift is affected by a change in the electronic state arising from the conformational change.⁹ NMR chemical shifts in the solid state, therefore, provide useful information about the electronic state and conformation of a biopolymer with a fixed structure.¹⁰

The present article concentrates on the use of solid state ^{13}C , ^{15}N , and ^{17}O NMR studies in the structural investigation of biopolymers such as polypeptides, proteins, and similar compounds.

2 SOLID STATE ^{13}C NMR OF POLYPEPTIDES AND PROTEINS

2.1 Synthetic Polypeptides

Synthetic polypeptides consist of repeating sequences of certain amino acids and their structures are not as complicated as those of proteins. For this reason, synthetic polypeptides are sometimes used as model compounds for proteins. Their conformations are classified as α -helix, β -sheet, ω -helix, and so on. High-resolution solid state ^{13}C NMR spectroscopy has proved to be a very powerful tool for determining the structure of polypeptides in the crystalline state.^{1,5–8} It has been demonstrated that the ^{13}C chemical shifts are related to particular conformations. Carbon-13 CP MAS NMR spectra of

Figure 1 Plots of the ^{13}C chemical shifts of oligo-L-Ala and poly-L-Ala against the number-average degree of polymerization ($\overline{\text{DP}}_n$)

solid poly(L-alanine) ($[\text{Ala}]_n$) show the C- α , C- β , and C=O carbon signals to be well resolved between the α -helix and β -sheet forms.¹¹ The ^{13}C chemical shifts are plotted against the number-average degree of polymerization in Figure 1. Clearly, ^{13}C chemical shifts of $[\text{Ala}]_n$ ($n > 16$) are unchanged for the peptides of various molecular weights within experimental error, and thus can serve to characterize the α -helix form. The chemical shifts of the C- α and carbonyl carbons of the α -helix are displaced significantly to high frequency (downfield) by 4.2 and 4.6 ppm, respectively relative to those of the β -sheet form, while the chemical shift of the C- β carbon of the α -helix is displaced to low frequency by about 5 ppm with respect to that of the β -sheet (−5.0 ppm). For this reason, the value of the ^{13}C chemical shift can be used to describe the local conformation.¹² In addition, the ^{13}C chemical shifts of randomly coiled poly(L-alanine) in trifluoroacetic acid solution have values between those of the α -helix and β -sheet forms.

The existence of such characteristic displacements of ^{13}C chemical shifts is not limited to the Ala residue. In Table 1 are summarized the ^{13}C chemical shift values of various amino acid residues in the α -helix and β -sheet forms.^{5,6} Here it is seen that the C- α and C=O peaks of the α -helix form are all displaced to high frequency with respect to those of the β -sheet form, which is consistent with the data of poly(L-alanine). The absolute ^{13}C chemical shifts of the C- α and C- β carbons are affected by the chemical structure of the individual amino acid residues and can be used effectively for conformational studies of particular amino acid residues in polypeptides and proteins. On the other hand, the C=O chemical shifts do not seem to be affected by residue structure and can be used for diagnosing the main chain conformation.

Poly(β -benzyl L-aspartate) (PBLA) in the solid state adopts various conformations such as a right-handed $\alpha(\alpha_R)$ -helix, a left-handed $\alpha(\alpha_L)$ -helix, a left-handed $\omega(\omega_L)$ -helix, and a β -sheet form depending upon the temperature. The measured values for the ^{13}C chemical shifts depend significantly on the conformations of the peptide as shown in Table 2.¹³ Variable temperature ^{13}C CP MAS NMR spectra of PBLA are shown in Figure 2.¹⁴ The temperatures of the conformational changes of PBLA are indicated in the Figure. From this, it is clear that

Figure 2 Variable temperature ^{13}C CP MAS TOSS NMR spectrum of poly(β -benzyl L-aspartate) in the solid state at various temperatures: dashed line, α_R -helix form; light solid line, ω_L -helix form; bold solid line; β -sheet form

the conformational changes α_R -helix $\rightarrow$ ω_L -helix $\rightarrow$ β -sheet occur with increasing temperature.

The conformations of polypeptides such as poly(L-alanine), polyglycine, and so on in the solid state are in many instances quite fixed. However, additional types of conformation can be formed when a small amount of guest glycine¹⁵ or L-Ala¹⁶ residues are incorporated into the host polypeptides. For example, solid state ^{13}C CP MAS NMR spectra of PBLA

containing $[3-^{13}\text{C}]\text{L-Ala}$ residues have been measured. The Ala C- β carbon shows significant displacements of the ^{13}C chemical shift depending on the conformational change.

Using the reference data, the helical sense of the ω -helix of poly(L-phenylalanine) has been shown to be right-handed, and this could not have been determined absolutely by X-ray diffraction. Furthermore, the side-chain conformation-dependent ^{13}C chemical shifts of this polymer and the L-phenylalanine residue in oligopeptides have been determined.¹⁷

The principal values of the ^{13}C chemical shift tensors (σ_{11} , σ_{22} , and σ_{33}) determined from the ^{13}C powder pattern spectrum are valuable as parameters for obtaining structural information which can be related to the electronic state more directly than the isotropically averaged value [$\sigma_{\text{iso}} = (\sigma_{11} + \sigma_{22} + \sigma_{33})/3$].¹⁰ Nevertheless, very few data are available for the ^{13}C chemical shift tensor for carbon atoms in peptides. There have been a few studies of conformation using ^{13}C chemical shift tensors of polypeptides in the solid state. Solid state ^{13}C CP MAS NMR spectra of a variety of polypeptides containing $[1-^{13}\text{C}]\text{glycine}$ residues as a minor component (<8%) have also been recorded. This was to obtain the ^{13}C isotropic average chemical shifts, and the principal values of the chemical shift tensors of the glycine (Gly) carbonyl carbon in β -sheet, α -helix, ω -helix, and 3_1 -helix forms.¹⁵ The last two conformations were obtained only when Gly residues were incorporated into the homopolypeptides. It was found that the magnitudes of displacements of chemical shifts upon conformational changes are larger for σ_{22} and σ_{33} than the

^aDP = degree of polymerization.

isotropic chemical shift values, while σ_{11} is almost unaffected by any conformational change.

A solid state ^{13}C NMR study of some polypeptides containing $[2-^{13}\text{C}]$ glycine residues has been carried out in order to clarify a conformational effect on the ^{13}C chemical shift tensors. It was found that the isotropic chemical shifts and principal values of the chemical shift tensor of Gly C- α incorporated in some homopolypeptides are displaced.

Hydrogen bonding plays an important role in the adoption of any specific conformation in peptides and polypeptides in the solid state. The effect of hydrogen bonding on the solid state ^{13}C chemical shifts of carbonyl carbons in peptides has been examined. Carbon-13 chemical shifts were determined for a series of oligopeptides containing glycine (Gly), L-Ala, L-valine, and L-leucine residues, for which the crystal structures were already available from X-ray diffraction studies. It was found that the ^{13}C chemical shifts of the carbonyl carbons in the $-\text{C}=\text{O} \cdots \text{H}-\text{N}-$ type of hydrogen bond move linearly to high frequency with a decrease in the hydrogen bond length ($R_{\text{N}-\text{O}}$) as $\delta = a R_{\text{N}-\text{O}} + b$ (ppm). For the Gly, L-Ala, L-valine, and L-leucine residues, a and b are -12.4 and 206 , -21.7 and 237.5 , -14.2 and 215.4 and -10.0 and 202.2 ppm, respectively.^{18,19} Using these relations, the hydrogen-bond length can be determined from the observed ^{13}C chemical shift values for the carbonyl carbons. These experimental results were explained by using ^{13}C chemical shift calculations based on the finite perturbation theory (FPT) intermediate neglect of differential overlap (INDO) method.

The conformational structures of poly(α -L-glutamic acid) [poly(Glu)], poly(α -L-aspartic acid) [poly(Asp)] and irregular poly(α,β -D,L-Asp) in the solid state have been studied by means of ^{13}C CP MAS NMR in conjunction with results from X-ray diffraction and infrared spectroscopy studies.²⁰ From these, it has been shown that poly(Glu) and poly(Asp) in the free acid form exhibit both α -helical and β -sheet forms, whereas the random coil form predominates in their sodium salts. Both the free acid and sodium salt of poly(α,β -Asp) exist predominantly in the random coil form. It turns out that the sodium salts are especially suitable for determining the NMR characteristics of the random coil conformation in the solid state.

2.2 Proteins

2.2.1 Fibrous Proteins

Since fibrous proteins generally have periodic amino acid sequence and higher order structures, the clarification of their

fine structure in the solid state becomes very important not only when discussing the physical and chemical properties, but also when obtaining information about the molecular design of synthetic polypeptides. Indeed, a comparison of some fibrous proteins and their model synthetic polypeptides has been carried out. The conformation-dependent ^{13}C chemical shifts are useful for the determination of the conformational features of fibrous proteins.

Silk fibroin is one of the fibrous proteins having a simple amino acid composition, and isotopic enrichment can be performed easily. More detailed analyses of static or dynamic structures have been made by solid state NMR.^{1,21,22} The amino acid composition of silk varies with the species of silkworm. In reflecting the higher Ala content of *Phylosamia cynthia ricini* fibroin it has been shown that the ^{13}C chemical shifts of the Ala residues of a dried sample, taken from the silk gland of *P.c. ricini*, are identical to those of the α -helical $[\text{Ala}]_n$. In contrast, the cocoon of *P.c. ricini* was found to have an antiparallel β -sheet form, as determined from the ^{13}C chemical shifts of the Ala and serine (Ser) residues. On the other hand, the ^{13}C peaks of the Ala and Gly residues of the silk II form of *Bombyx mori* silk fibroin are in good agreement with those of $[\text{Ala-Gly}]_n$ II as well as $[\text{Gly}]_n$ II and $[\text{Ala}]_n$ in the β -sheet form. The ^{13}C chemical shifts of samples taking the silk I form are significantly displaced from those of the silk II form. Models for the silk I structure of *B. mori* silk fibroin have been proposed on the basis of ^{13}C NMR data, X-ray diffraction data, and conformational energy calculations.

Collagen is composed of a triple-stranded helix. The individual triple chains are composed of the repeating pattern, $[\text{Gly-X-Y}]_n$, where X and Y are frequently occupied by proline (Pro) and hydroxyproline residues, respectively. Torchia and co-workers^{23,24} have reported substantial work on the molecular dynamics of collagens by means of multinuclear solid state MR, using isotopically labeled samples which were obtained by cultivation techniques. Saito et al.²⁵ have found that most of the ^{13}C signals of collagen fibrils from bovine tendon and skin are in good agreement with those of $[\text{Pro-Gly-Pro}]_n$, although some peaks characteristic of the collagen are slightly displaced from those of the model polypeptides. All of the peaks of collagen fibrils have been assigned on the basis of computer simulation by utilizing amino acid composition and chemical shift data from the solid state and solution.

Carbon-13 CP MAS NMR spectra of tropomyosin, one of the muscle proteins, were measured in the solid state, in order to elucidate the higher order structure of the protein via the observation of the ^{13}C chemical shifts of the amino acid residues and their mobility. The higher order structure of tropomyosin is a right-handed α -helix coiled-coil structure,

Figure 3 A schematic picture of the cross-section of the coiled-coil structure in tropomyosin (top), and the typical ^{13}C CP MAS NMR spectrum of tropomyosin at room temperature (bottom)

which contains two different sites. These are characterized by an internal hydrophobic site and an external hydrophilic site (Figure 3). A typical ^{13}C CP MAS NMR spectrum for tropomyosin in the solid state is shown in Figure 3.²⁶ Since the Ala residue is one of the major components, the ^{13}C signal which appears at 15–17 ppm can be assigned readily to the Ala C- β carbons, and it is seen that this signal consists of two peaks. Figure 4 shows the expanded Ala C- β signal, measured using the inversion–recovery method. These peaks indicated that there are at least two kinds of Ala C- β carbons. Furthermore, the carbon atoms contributing to the peak at 15.8 ppm have a larger value of T_1 than those at 16.7 ppm. This indicates that the former carbons are more mobile than the latter carbons, because the Ala C- β carbons in tropomyosin have correlation times with values appearing in an extremely narrow region at room temperature. The distance between the two α -helical axes in the coiled-coil structure is shorter than in coiled-coil helices which are packed in parallel in native muscle, as shown from X-ray studies. Therefore, it can be argued that the mobility of the Ala C- β carbon atoms in the internal site is expected to be more restricted than that in the external site. The two peaks at 15.8 and 16.7 ppm therefore are assigned to the Ala C- β carbons in the external and internal sites of the coiled-coil structure, respectively.

Native wool fiber consists of intermediate filaments composed of low-sulfur-containing proteins which are embedded in a nonfilamentous matrix. The nonfilamentous matrix

Figure 4 The expanded ^{13}C NMR spectra of the Ala C- β carbon atoms of tropomyosin, measured using the inversion–recovery method at room temperature. Recovery time, t : (a) 10 ms; (b) 500 ms; (c) 3500 ms

usually consists of two classes of proteins; one is a high-sulfur-containing protein and the other is a protein containing Gly and tyrosine (Tyr) residues. Wool keratin can be divided into three main fractions after reducing the disulfide bonds and protection of the resulting thiol groups with iodoacetic acid to form *S*-carboxymethylkerateine (SCMK). The solid state ^{13}C CP MAS TOSS NMR spectra of wool and four kinds of SCMKs extracted from low-sulfur fractions (SCMKA), helix-rich fragments (SCMKA-hf), high-sulfur fractions (SCMKB), and high-Gly-Tyr fractions (HGT) are shown in Figure 5.^{27,28} For characterization of the main-chain conformation of polypeptides and proteins in the solid state, it is very useful to use the ^{13}C chemical shift value of the main-chain carbonyl carbon, because it is strongly influenced by the conformation of the main chain but not by the type of amino acids and/or a specific amino acid sequence. Hence, it can be argued that the lineshape of the ^{13}C signals in the carbonyl region for proteins reflects the main-chain conformation.

The carbonyl ^{13}C signal can be resolved into four peaks by computer fitting. The relative intensity of the high-frequency peak at about 176 ppm corresponds to the proportion of the α -helix component, because this peak comes from the main-chain carbonyl carbons in the α -helix form. The proportion of

Figure 5 ^{13}C CP MAS TOSS NMR spectra of (a) wool, (b) SCMKA, (c) SCMKA-hf, (d) SCMKB, and (e) HGT, and their expanded spectra of the carbonyl carbon region. Arg = arginine, Thr = threonine, Val = valine, Ile = isoleucine, Cys = cysteine, Phe = phenylalanine

the α -helix component increases in the order: wool, SCMKA, SCMKA-hf. On the other hand, the low-frequency peak at 172 ppm is characteristic of the main-chain carbonyl carbons in the β -sheet form. On the basis of the above assignment, it can be said that the β -sheet form is predominant in SCMKB and HGT. These findings are also confirmed from the peaks in other carbon regions. Furthermore, it is suggested that the coiled-coil structure exists in wool, SCMKA, and SCMKA-hf,

because the ^{13}C chemical shift values of the Ala C- β carbons in these samples coincide, within experimental error, with that of the Ala residue located in the internal site of the coiled-coil structure in tropomyosin.

This conformational analysis, using conformation-dependent ^{13}C chemical shifts, has been applied to investigate the conformational transition of SCMKA induced by stretching, heating, or steam-treating. The β -sheet form appears and the proportion

Figure 6 Expanded ^{13}C CP MAS TOSS NMR spectra for the carbonyl carbon region in SCMKA films cast from aqueous solution

of the α -helix form decreases upon stretching and steam-treating as shown in Figure 6.²⁸ For the SCMKA heated at 200 °C for 3 h in vacuo, the ^{13}C CP MAS spectrum shows that each peak is broader than those of other treated specimens. This indicates the existence of various conformations and/or different microenvironments in the heated SCMKA. Thus, it can be said that the random coil form appears by heating. From X-ray diffraction measurements, the α -helix form completely vanishes in SCMKA heated under the same conditions. However, Figure 6 shows that the α -helix form remains to an appreciable extent in the heated sample, although the random coil form also appears. The difference between the results from X-ray diffraction and NMR spectroscopy studies suggests that only the packing of the ordered structure (the α -helix form) in SCMKA is disrupted by heating, but that the secondary structure is retained. On the other hand, in the case of the structural transition for the same protein, the change of the lineshape for the α -methine carbons can be attributed mainly to the conformational change.

The dynamics and structure of mouse keratin intermediate filaments has been investigated by solid state ^{13}C and ^2H NMR spectroscopy, using isotopically labeled samples.²⁹

2.2.2 Membrane Proteins

The structural and dynamic analysis of membrane proteins is readily achieved by solid state ^{13}C NMR. The reasons are

as follows: firstly, biological membranes greatly restrict the motion of embedded proteins and consequently are difficult to study by solution NMR methods; secondly, only a few membrane proteins have been crystallized and studied by X-ray diffraction methods; thirdly, if the membrane protein is uniaxially oriented in the lipid, there is the advantage of being able to determine the structure at the atomic level by NMR as well as X-ray crystallography. Further, since phospholipids coexist in many cases in membranes, the NMR method is still suitable because of its ability to observe selectively by means of isotopic labeling, multinuclear MR, and utilizing the differences of relaxation times. Thus phospholipids, for example, are readily and selectively studied by solid state NMR methods using specifically ^{31}P NMR.³⁰

The ^{13}C CP MAS spectra of ^{13}C -labeled gramicidin A (GA) were measured to determine directly the structure of this peptide in a lipid membrane.³¹ The seven GA analogs, each labeled at a single carbonyl group of each of some amino acid residues, were synthesized by the solid phase method. These ^{13}C -labeled GAs were incorporated into aligned multilayers of dimyristoylphosphatidylcholine or diether lipid bearing 14- or 16-carbon chains, at a 1:15 peptide:lipid molar ratio. Carbon-13 CP NMR spectra were obtained at several temperatures and over a range of sample orientations with respect to the spectrometer magnetic field. The observed chemical shielding anisotropies indicate that all of the labeled carbonyl bonds are oriented almost parallel to the molecular long axis and perpendicular to the lipid bilayer plane. These orientations are consistent with GA forming a $\beta 6.3$ single-strand helix that is oriented parallel to the methylene chains of the lipid molecules. Comparison of the linewidths from labeled residues that are in the innermost turn of the helix, and in the turn nearest the lipid bilayer surface suggests that although the peptide behaves largely as a right-handed barrel, segments of the peptide close to the membrane surface possess greater motional freedom.

Bacteriorhodopsin and rhodopsin are integral membrane proteins that contain the vitamin A aldehyde, retinal, as a photoreactive chromophore. Many solid state NMR studies on the structure and environment of the retinal chromophore in these proteins have been reported, using mainly specifically ^{13}C -labeled retinals.^{2,32,33} It may reasonably be said that the structure of retinal in bacteriorhodopsin and rhodopsin has been determined by solid state NMR. Hence, solid state NMR is an extremely important experimental procedure in investigating the mechanism of sight. Most recently, the spectrum of ^{13}C -labeled bacteriorhodopsin in purple membranes was recorded. On the basis of the ^{13}C CP MAS NMR experiments, a discussion has been presented of the change of the manner of mutual orientation between α -helices as induced by hydration/dehydration.

Also, soluble proteins such as enzymes, conjugated proteins such as glycoproteins, and proteins which are in more complex systems have been investigated by solid state NMR.^{34–36}

3 SOLID STATE NMR STUDIES OF ^{15}N IN SYNTHETIC POLYPEPTIDES

It has been demonstrated that the isotropic ^{15}N chemical shifts of systems such as poly(Gly) (PG), poly(L-Ala), poly(L-leucine), poly(L-isoleucine) poly(L-valine), poly

Figure 7 Diagram of the observed isotropic ^{15}N shielding of some homopolypeptides $[\text{X}]_n$ with various conformations (α -helix, β -sheet, α_L -helix, ω_L -helix, PG I, PG II, PP I, and PP II forms). Leu = leucine, Ile = isoleucine, Val = valine, Glu = glutamic acid

(L-phenylalanine), poly(γ -methyl L-glutamate), poly(β -benzyl L-aspartate) and poly(L-Pro) (PP) in the peptide backbone of polypeptides in the solid state exhibit a significant conformation-dependent change. Both experimental observation and theoretical calculation confirm this.^{37–39} The σ_{iso} for the α -helix form (97.0–99.2 ppm) appears to low frequency by about 1.2–10.0 ppm with respect to that for the β -sheet form (99.5–107.0 ppm) of polypeptides, which obviously depends on the structure of the individual amino acid residue, as shown in Figure 7 (relative to $^{15}\text{NH}_4\text{NO}_3$). Some ^{15}N chemical shift differences are rather small, but are meaningful in the context of polypeptides. The variations of the σ_{iso} for various kinds of polypeptides are about 2.5 ppm in the α -helix form and about 7.5 ppm in the β -sheet form. In addition, the σ_{iso} of the β -sheet form of the L-leucine, L-valine, and L-isoleucine residues, which possess alkyl side chains, appear to high frequency with respect to that of the L-Ala residue. In contrast, the σ_{iso} value for the β -sheet form of the L-Asp(OBzl), L-Glu(OBzl), and L-Glu(OMe) residues (where Glu = glutamic acid), which possess a side-chain ester, is to low frequency with respect to that of the L-Ala residue. These results indicate that the ^{15}N chemical shift difference between the α -helix and β -sheet forms depends on the side-chain structure of individual amino acid residues.

Further, σ_{iso} gives information about the helix sense (α_R -helix or α_L -helix) of poly(β -benzyl L-aspartate) (ω -helix: 99.2 ppm; α_L -helix: 97.0 ppm).⁴⁰ In addition, the ^{15}N chemical shift value of PBLA with low molecular weight (β -sheet form) is identical with that of PBLA with high molecular weight (β -sheet form), indicating that the ^{15}N chemical shift of solid polypeptides is independent of the chain length, if no conformational changes occur. Accordingly, the ^{15}N chemical shift depends mainly on the conformation and side-chain structure of individual amino acid residues. In order to support this view theoretical calculations of ^{15}N chemical shifts are required, using the electronic states derived by quantum chemical methods. The relative ^{15}N NMR chemical shift of a dipeptide fragment forming hydrogen bonds with two formamide molecules has been calculated using the FPT INDO theory.³⁷

The relation between the isotropic ^{15}N chemical shift or chemical shift tensor and the structures of various kinds of synthetic copolypeptides in the solid state have been studied.^{38–40} It was found that the ^{15}N chemical shifts indicate strong neighboring sequence effects.

An analytical method for the determination of dihedral angles of the GA backbone from solid state ^{15}N NMR spectroscopic data has been demonstrated.^{31,41} Advantage is taken of the ^{15}N – ^1H and ^{15}N – ^{13}C dipolar interactions as well as the ^{15}N chemical shift interaction in the oriented samples. The dihedral angles for the L-Ala₃ site are determined by obtaining the NMR data for both the Gly₂–L-Ala₃ and L-Ala₃–D-leucine₄ peptide linkages. Two possible sets of torsion angles for the L-Ala₃ site are obtained ($\phi, \psi = -129^\circ, 153^\circ$ and $-129^\circ, 122^\circ$), both of which are consistent with a right-handed α -helix. In addition, the dynamics of the backbone of GA in dimyristoylphosphatidylcholine bilayers have been investigated using solid state ^{15}N NMR.⁴¹ Nitrogen-15 CP NMR spectra of single-site ^{15}N -labeled GA at 8 °C were analyzed to yield a spatial model for local backbone motion. This model includes the axis of motion, the mean orientation, and the maximum amplitude of displacement for individual peptide planes. Specific sites in the first turn of the amino terminus were investigated, with emphasis on the L-Ala₃ and D-leucine₄ linkages, for which the orientation of the ^{15}N chemical shift tensor with respect to the molecular frame has been determined.

4 SOLID STATE ^{17}O NMR OF SYNTHETIC POLYPEPTIDES

The oxygen atom is an important atom in the hydrogen bonding structure in peptides and polypeptides. Nevertheless, a solid state ^{17}O NMR study of peptides and polypeptides has never been carried out, to our knowledge. This is due to the very low sensitivity of solid state ^{17}O NMR measurements which arises for two reasons. One is that the ^{17}O nucleus is in very low natural abundance, 0.037%. The other is that the ^{17}O nuclear spin quantum number (I) is $\frac{5}{2}$, which is a quadrupolar nucleus, and so the ^{17}O signal is broadened by nuclear quadrupolar effects in the solid. On the other hand, solution state ^{17}O NMR spectroscopy has been employed successfully to elucidate a number of structural problems in organic chemistry,⁴² because the ^{17}O signal becomes very sharp due to the removal of quadrupolar interaction by isotropic fast reorientation in solution. For example, as the oxygen atom is directly associated with the formation of hydrogen bonds, hydrogen bonding for the carbonyl group

in various compounds often results in large low-frequency shifts of the carbonyl ^{17}O NMR signal.⁴³ From these results, solution state ^{17}O NMR has been established as a means of investigating structural characterizations.

Clearly therefore, solid state ^{17}O NMR does offer a unique opportunity for understanding the hydrogen-bonding structure in solid peptides and polypeptides. Kuroki et al.⁴⁴ have observed high-resolution ^{17}O NMR spectra of systems with a wide range of hydrogen bond length, of PG I, PG II, glycylglycine (GlyGly) and glycylglycine nitrate (GlyGly·HNO₃) in the solid state, in order to obtain three kinds of NMR parameters: chemical shift, the quadrupolar coupling constant (e^2qQ/h) and the asymmetric parameter (η_Q), and to understand the relationship between the hydrogen bonding structure and these NMR parameters.

Static ^{17}O CP NMR spectra of GlyGly were observed at 36.6, 54.2, and 67.8 MHz. The spectra at 36.6 and 54.2 MHz consist of two major split signals, but that at 67.8 MHz becomes one major signal. Such splitting comes

from the quadrupolar interaction. By computer simulation, the quadrupolar coupling constant e^2qQ/h was determined to be 8.55 MHz. This value is much larger than that for the amide ^{14}N nitrogen nucleus (1.11 MHz). It is seen that the NMR spectra depend strongly on the measurement frequency because the quadrupolar effect depends on the measurement frequency, and the broadening of the ^{17}O NMR signal is further increased by the quadrupolar effect as the measurement frequency is decreased. Thus, it is clear that high-frequency measurements are needed for quadrupolar nuclei such as ^{17}O .

Figure 8 shows 67.8 MHz static ^{17}O CP NMR spectra of PG I, PG II, GlyGly, and GlyGly·HNO₃ (points), compared with the computer simulations (continuous lines). The ^{17}O NMR parameters of PG I, PG II, GlyGly, and GlyGly·HNO₃ obtained by computer simulations are shown in Table 3. From these results, the δ_{11} , δ_{22} , and δ_{33} values of the samples were found to change from 546 to 574 ppm, 382 to 425 ppm, and -132 to -101 ppm, respectively. The magnitude of the chemical shift change is much larger than that of the carbonyl

Figure 8 ^{17}O 67.8 MHz CP static NMR spectra of GlyGly·HNO₃ (a), GlyGly (b), PG I (c), and PG II (d), together with theoretically simulated spectra

Table 3 Determined ^{17}O NMR Parameters of Solid Peptides and Polypeptides Containing a Gly Residue

Sample	e^2qQ/h (MHz)	η_Q	Chemical shift tensor (ppm)						Angle Δ^a (deg)		
			δ_{11}	δ_{22}	δ_{33}	δ_{iso}	$\Delta\delta^b$	η^c	α	β	γ
<i>Polypeptides</i>											
PG II	8.30	0.29	562	410	−108	288	396	0.38	92	89	−81
PG I	8.55	0.26	574	425	−101	299	400	0.37	100	91	−79
<i>Oligopeptides</i>											
GlyGly	8.55	0.45	546	382	−132	265	397	0.41	94	90	−87
GlyGly·HNO ₃	8.75	0.47	559	408	−127	280	407	0.37	94	89	−81

^aAngle Δ indicates the Euler angles between the principal axes of the quadrupolar tensor and the chemical shift tensor.

^b $\Delta\delta = \delta_{\text{iso}} - \delta_{33}$.

^c $\eta = (\delta_{11} - \delta_{22})/\Delta\delta$.

^{13}C and amide ^{15}N chemical shift. Every $\Delta\delta$ defined by $\Delta\delta = \delta_{33} - \delta_{\text{iso}}$, is about 400 ppm, which is much larger than that of the carbonyl ^{13}C and amide ^{15}N chemical shifts by about 170, 100 ppm, respectively. Every η value, defined by $\eta = (\delta_{22} - \delta_{11})/\Delta\delta$, is roughly 0.4. These values are common to the carbonyl oxygen in peptides. Although the chemical shift tensor is axially symmetric ($\delta_{11} = \delta_{22}$) for the case of the carbonyl oxygen of L-Ala as reported by Fiat and co-workers,^{45,46} the chemical shift tensor of the carbonyl oxygen in the peptides considered here is not axially symmetric.

The e^2qQ/h values change from 8.30 to 8.75 MHz. These values are larger than the e^2qQ/h value of χ for L-leucine, which is 8.0 MHz at 190 K.⁴⁶ The η_Q values of polypeptides such as PG I and II are 0.26 and 0.29, and the η_Q values of oligopeptides such as GlyGly and GlyGly-HNO₃ are 0.45 and 0.47, respectively. The difference may come from a difference in molecular packing between them. Further, it is found that the principal axis of the quadrupolar tensor and the principal axis of the ^{17}O chemical shielding tensor for the carbonyl oxygen of the peptides and polypeptides are not coincident with each other. From these experimental results it can be said that each of the above NMR parameters is strongly influenced by the electronic structure of molecules.

So far, there has been little study aimed at determining the direction of the principal axes of the electric field gradient tensor and the chemical shielding of carbonyl oxygen of peptides and polypeptides from NMR experiments. The direction of the principal axes of the chemical shielding of the carbonyl oxygen of peptides and polypeptides has been calculated using FPT-MNDO-PM3 methods. It was found that the σ_{22} component lies approximately along the C=O bond, the σ_{11} component is aligned in the direction perpendicular to the C=O bond on the peptide plane, and σ_{33} which is the most shielded component is aligned in the direction perpendicular to the peptide plane. In the case of the electric field gradient tensor of the carbonyl oxygen, it was shown that the V_{22} component lies approximately along the C=O bond, the V_{33} component is aligned in the direction perpendicular to the C=O bond on the peptide plane, and the V_{11} component is aligned in the direction perpendicular to the peptide plane. These results show that the largest component V_{33} of the electric field gradient lies along the molecular chain direction. The relationship between the electric field gradient tensor and the chemical shielding obtained by this calculation agree with the experimental results.

The plot of the observed e^2qQ/h values vs. the hydrogen bond length shows that the e^2qQ/h values decrease linearly

with a decrease in the hydrogen-bond length ($R_{\text{N-O}}$) (in Å) as expressed by e^2qQ/h (MHz) = 5.15 + 1.16 $R_{\text{N-O}}$. This shows that the decrease of the hydrogen-bond length leads to a decrease in electric gradient (q). The value of q is very sensitive to the hydrogen-bond-length change. From this relationship it is apparent that the hydrogen-bond length can be determined by the observation of the e^2qQ/h value. The plot of the observed isotropic ^{17}O chemical shift values (δ_{iso}) against the hydrogen-bond length ($R_{\text{N-O}}$) shows that the δ_{iso} values in both peptides and polypeptides move upfield with a decrease in the hydrogen-bond length ($R_{\text{N-O}}$). The plot of the observed principal values of ^{17}O chemical shifts against the hydrogen-bond length ($R_{\text{N-O}}$) also shows every principal value in both the peptides and polypeptides and moves to low frequency with a decrease in the hydrogen-bond length ($R_{\text{N-O}}$).

From these experimental findings, it is clear that ^{17}O NMR spectroscopy will become a powerful tool for elucidating the hydrogen-bonding structure in solid peptides and polypeptides.

1 INTRODUCTION

Nuclear shielding data offer microscopic information about the stereochemical and crystal structures of polymers, which in turn are important factors in understanding physical properties. Details of electronic structure can also be deduced from nuclear shielding data, and this is also important in controlling physical properties.¹ In order to obtain information about the electronic structure of polymers from nuclear shielding data, it is necessary to use a theoretical approach in addition to an experimental one.

In general, there are two possibilities for obtaining such information by theoretical methods. One is to use a fragment of polymer such as a dimer, trimer, etc. for theoretical calculations. Such an approach is useful, because the nuclear shielding is sometimes governed by the local electronic structure. However, there is doubt whether the electronic structure obtained from the model compound appropriately reproduces that of the polymer chain. Another approach is to employ directly an infinite polymer chain with a periodic structure. This leads to the application of the tight-binding (TB) molecular orbital approximation, which was developed in the field of solid state physics.² Its advantages are that it treats the polymer directly and that relatively long range intrachain interactions such as hydrogen bonding in the α -helix form of polypeptides can be easily taken into account.

In using the model compound approach, the electronic structure of large chains can be visualized by drawing the orbital energies associated with chains of increasing length. On the other hand, for an infinite polymer chain, the energy levels are built up as a continuous band structure. As the rotation about the bond is strongly restricted in solid polymers, the periodicity of the polymer chain is retained. From the point of view of calculating nuclear shielding, use of the TB model for calculations of the electronic structures of polymers has been successful. Here we describe the basic ideas for deducing the electronic structure and nuclear shielding of solid polymers by the TB approximation.

2 THEORETICAL ASPECTS OF ELECTRONIC STATE AND NUCLEAR SHIELDING IN SOLID POLYMERS

Polymers can be characterized by a possible periodicity in their conformational structure and a large number of electrons. In this system, the potential energy that an electron experiences is periodic. Periodic systems have the advantage of translational symmetry when compared with aperiodic systems. It is possible to exploit this symmetry in order to reduce to reasonable proportions the formidable task of computing the electronic states of an extended system. The TB molecular orbital model is employed to describe the electronic structure of linear periodic polymers within the framework of a 'linear combination of atomic orbitals' approximation for electronic eigenfunctions. By means of Bloch's theory,³ the eigenfunction $\Phi_n(k)$ for an electron at position r , belonging to the n th crystal orbital is given by

$$\Phi_n(k) = N^{-1/2} \sum_{j=-(N-1)/2}^{(N-1)/2} \sum_{v=1}^s e^{ijkb} C_{vn}(k) \phi_v(r - jb) \quad (1)$$

where k is the wavenumber, v is an orbital index for the j th cell, s is the total number of atomic orbitals in a given cell, N is the total number of cells considered, and b is the unit vector of translational symmetry. In equation (1) $\phi_v(r - jb)$ represents the v th atomic orbital in the j th cell and $C_{vn}(k)$ its expansion coefficient in the linear combination of atomic orbitals. The limits of k , within a given Brillouin zone, are $-\frac{1}{2}\pi$ and $\frac{1}{2}\pi$. Using equation (1), the total energy E of the polymer can be expressed as

$$E(k) = \frac{\text{occ}}{n} \langle \Psi_n(k) | \hat{\mathcal{H}} | \Psi_n(k) \rangle \quad (2)$$

where $\Psi_n(k)$ is the Slater determinant composed of the $\Phi_n(k)$. $\hat{\mathcal{H}}$ is the Hamiltonian, consisting of terms representing the kinetic energy, the potential energy of the electronic field of the polymer, and the electron repulsion energy. The advantage of equation (1) is that calculation of the electronic structure of an infinite polymer can be reduced to the calculation for a unit cell (monomer unit) interacting with all other unit cells, using the periodicity of the polymer.

In general, calculations on small molecules using ab initio MO methods can provide very satisfactory estimates of nuclear shielding.¹ For larger monomeric species, semiempirical molecular orbital calculations such as CNDO/2 and INDO/S are still the workhorses. The diagonal and off-diagonal elements of the Fock matrix, $F_{\mu\mu}$ and $F_{\mu\mu'}$, respectively, based on CNDO/2, are expressed as follows:

$$\begin{aligned} F_{\mu\mu}(k) = & -\frac{1}{2}(I_\mu + A_\mu) + \frac{1}{2}(1 - P_{\mu\mu})\gamma_{AA}^{00} \\ & + \sum_B \sum_{j=-M}^M (P_B - Z_B)\gamma_{AB}^{0j} \\ & + 2K_\pi \beta_A \sum_{j=1}^M S_{\mu\mu}^{0j} \cos kj - \sum_{j=1}^M \gamma_{AA}^{0j} P_{\mu\mu}^{-jR} \cos kj \end{aligned} \quad (3)$$

$$\begin{aligned} F_{\mu\mu'}(k) = & \frac{1}{2}K_\pi(\beta_A + \beta_B) \sum_{j=-M}^M S_{\mu\mu'}^{0j} e^{ikj} \\ & - \frac{1}{2} \sum_{j=-M}^M P_{\mu'\mu}^{-jR} \gamma_{AB}^{0j} e^{ikj} \end{aligned} \quad (4)$$

Figure 1 Electronic band structure of polyethylene with *trans* zigzag conformation calculated using CNDO/2 TB MO

where I_μ and A_μ are the ionization potential energy and electron affinity, respectively, γ_{AB} represents the Coulomb repulsion integral between the atomic orbital μ on atom A in the original cell and the atomic orbital μ' on atom B in the j th cell. $S_{\mu\mu'}^{0j}(k)$ is the overlap integral between the μ th atomic orbital in the original cell and the μ' th atomic orbital in the j th cell. $P_{\mu\mu'}$ is the bond order matrix, P_B is the electron density on atom B, $P_{\mu\mu'}^{-jR}$ is the bond order matrix between the μ th atomic orbital in the original cell and the μ' th atomic orbital in the $\pm j$ th cell, and Z_B is the core charge of atom B. K_π is a correction factor for the $\pi-\pi$ electron interaction.^{4,5}

By solving the Fock matrix defined by equations (3) and (4), the expansion coefficients in equation (1) can be obtained. These expansion coefficients and energies are dependent on k , which leads to a band structure for the polymer chain. Figure 1 shows the calculated band structure of polyethylene with a *trans* zig-zag conformation. As only six valence electrons in a monomer unit cell are included in the calculation, the corresponding six valence bands can be seen in Figure 1. Calculation with model compounds gives discrete energy levels. In a series of homogeneous molecules, the number of energy levels increases with the molecular size, and correspondingly the separation between these energy levels decreases. For an infinite polymer chain, the energy level is a continuous band structure, as shown in Figure 1. The electronic structure of solid polymers is characterized by this band structure, with a dependence of the energy level on k .

The nuclear shielding for the various nuclei in a given macromolecule can be calculated from the electronic band structure obtained, $C_{vm}(k)$, and $E_n(k)$. In general, the nuclear shielding can be written as¹

$$\sigma = \sigma^d + \sigma^p + \sigma' \quad (5)$$

where σ^d and σ^p are diamagnetic and paramagnetic contributions, respectively, and σ' is the contribution from neighboring atoms. For a carbon atom, σ' is much less than 1 ppm, and can be considered negligible. Thus, σ can be estimated as the sum of σ^d and σ^p . Based on the TB MO, σ^d and σ^p are obtained

by the sum-over-states method as follows:⁵⁻⁷

$$\sigma_A^d(k) = \frac{\mu_0 e^2}{6\pi m_e^2} \sum_v^A \sum_{v'}^A P_{vv'}(k) \langle \phi_v(r) | r^{-1} | \phi_{v'}(r) \rangle \quad (6)$$

$$\begin{aligned} \sigma_{A,\alpha\beta}^p(k) = & -\frac{\mu_0 h^2 e^2}{4\pi m_e^2} \sum_m^{\text{occ}} \sum_n^{\text{unocc}} \sum_j^A \langle r^{-3} \rangle_{2p} ({}^1 E_m^n - {}^1 E_0)^{-1} \\ & \times \sum_j^B \sum_l^B [X(k, j, m, n, \beta, \gamma) X(l, m, n, \gamma, \alpha) \\ & - Y(j, m, n, \beta, \gamma) Y(l, n, m, \gamma, \alpha) \\ & + X(j, m, n, \gamma, \alpha) X(l, n, m, \beta, \gamma) \\ & - Y(j, m, n, \gamma, \alpha) Y(l, n, m, \beta, \gamma)] \end{aligned} \quad (7)$$

Here e is the charge and m_e the mass of the electron, μ_0 is the permeability of free space,

$$P_{vv'}(k) = \sum_m^{\text{occ}} C_{vm}^*(k) C_{v'm}(k) \quad (8)$$

where m refers to the number of occupied crystal orbitals and n to those that are unoccupied, E_0 is the electronic energy of the ground state, and E_m^n is the energy of the state created by promoting an electron from orbital m to orbital n . j and l are atomic orbitals on centers A and B, respectively, and

$$X(j, m, n, \beta, \gamma) = C_{jm}^{\text{R}\beta} C_{jn}^{\text{I}\gamma} + C_{jn}^{\text{R}\beta} C_{jm}^{\text{I}\gamma} - C_{jn}^{\text{R}\gamma} C_{jm}^{\text{I}\beta} - C_{jm}^{\text{R}\gamma} C_{jn}^{\text{I}\beta} \quad (9)$$

$$Y(j, m, n, \beta, \gamma) = C_{jm}^{\text{R}\beta} C_{jn}^{\text{R}\gamma} + C_{jn}^{\text{R}\gamma} C_{jm}^{\text{R}\beta} - C_{jn}^{\text{I}\beta} C_{jm}^{\text{I}\gamma} - C_{jm}^{\text{I}\gamma} C_{jn}^{\text{I}\beta} \quad (10)$$

where α , β , and γ refer to the x , y , and z components of the shielding tensor in cyclic order, and R and I indicate the real and imaginary parts of the coefficients $C_{vm}(k)$. As shown by equations (6) and (7), the nuclear shielding is calculated as a function of k . In order to be able to compare the calculated and experimental values of the nuclear shielding, it is necessary to average the calculated data over k , within the first Brillouin zone, as given by

$$\sigma = \int_{-\pi/b}^{\pi/b} \sigma(k) D(k) dk \quad (11)$$

where $D(k)$ is the density of states, namely, the number of states per unit amount of energy. Thus, the nuclear shielding can be obtained through the electronic band structure of polymers—especially solid polymers.

The quantities calculated using equations (6) and (7) are nuclear shieldings σ , and so the negative sign means deshielding. On the other hand, a negative sign for the observed chemical shift δ means an increase in shielding. Hereinafter, calculated and observed shieldings are expressed as shielding and chemical shift, respectively. The absolute value of the calculated shielding should be compared directly with the observed chemical shift.

3 INTERPRETATION OF NUCLEAR SHIELDING BY THE TB METHOD

The shielding of ^{13}C reflects the magnetic environment of the atom considered, and this depends on the conformation, configuration, and crystal structure of polymers. In order to understand ^{13}C shielding, examples illustrating the applications of TB MO methods to some polymers will be described.

Figure 2 Dependence of the calculated ^{13}C NMR shielding of polyoxymethylene on dihedral angle ψ

3.1 Conformation

It is known from an X-ray diffraction study that a polyoxymethylene chain in the crystalline region takes an all-*gauche* conformation with a 9/5 helix.⁸ However, in the noncrystalline region, the structure has not yet been determined exactly, because of the complicated conformation of the chain. It has been reported that the observed ^{13}C chemical shifts of polyoxymethylene in crystalline and noncrystalline regions appear at 88.5 and 89.5 ppm, respectively.⁹ Figure 2 shows the dependence of the calculated isotropic ^{13}C shielding on the dihedral angles ψ within the framework of CNDO/2 TB MO.

The isotropic shielding of ^{13}C increases as ψ is increased from 50° to 90° , and the shielding decreases through a minimum value as ψ is increased from 90° to 180° . The values of 60° and 180° for ψ correspond to the all-*gauche* and all-*trans* conformations, respectively. The calculated isotropic ^{13}C shielding of the all-*gauche* conformation appears at lower frequency by about 1 ppm than that of the all-*trans* conformation. Dividing the difference of ^{13}C shielding between all-*gauche* and all-*trans* conformations, for the diamagnetic term, the difference between the all-*gauche* and all-*trans* conformations is 0.1 ppm, and for the paramagnetic term the corresponding difference is 0.9 ppm. The contribution to the relative ^{13}C shielding is due mainly to a change in the paramagnetic term. The diamagnetic term is determined only by the ground state, whereas the paramagnetic term involves interactions between the ground and excited states, as seen from equations (6) and (7). Thus, the observed chemical shift difference between the crystalline and noncrystalline regions

comes from a variable interaction due to a conformational change. Therefore, it can be argued that the calculated value confirms well the experimental finding that the ^{13}C shielding for the crystalline region is greater by about 1 ppm than that for the noncrystalline region.

Calculated values of $\Delta\sigma$ ($=\sigma_{yy} - \sigma_{zz}$; spectrum breadth) for the all-*gauche* and all-*trans* conformations are 37.7 and 1.8 ppm, respectively. $\Delta\sigma$ for the all-*gauche* conformation is much larger than that for the all-*trans* conformation. On the other hand, the experimental values of $\Delta\delta$ for the crystalline and noncrystalline regions are about 35 ppm and 7–10 ppm, respectively.⁹ The calculated and experimental values agree relatively well with each other. The fact that the calculated value of $\Delta\sigma$ for the all-*trans* conformation is rather small suggests that the electronic environment around the carbon nucleus considered here is relatively symmetric. The small observed value for $\Delta\delta$ may be due mainly to the high symmetry of the electronic environment in addition to the averaging of ^{13}C shielding anisotropy with molecular motion. Further, we are concerned with the behavior of δ_{22} , whose value is obtained from the apex of the tent-like powder pattern. In the experimental data, δ_{22} for the crystalline region appears at about 5 ppm to low frequency when compared with that for the noncrystalline region. However, the calculated value of σ_{xx} for the all-*gauche* conformation appears at lower frequency by about 2.5 ppm when compared with that for the all-*trans* conformation. Thus, the calculation explains the experimental observation reasonably, despite the rough assumption of an all-*trans* conformation for the noncrystalline region.

There has also been some interest in polypeptides. It has been demonstrated that the ^{13}C chemical shifts of C- α , C- β , and the carbonyl carbons are displaced by up to 7 ppm, depending on the particular conformations such as α -helix and β -sheet. Such conformation-dependent chemical shifts of ^{13}C can be understood through changes of the electronic band structure varying with the dihedral angles (ϕ and ψ) of the skeletal bond.

Table 1 shows the calculated and observed ^{13}C shieldings of a polyglycine chain with forms I and II.⁷ The observed carbonyl ^{13}C signal for form I is shielded by about 4 ppm compared with that for form II. The calculated ^{13}C shielding for form I is larger by about 11 ppm than that for form II, which matches the experimental finding. There is no significant difference between the methylene ^{13}C chemical shifts for forms I and II within experimental error. At this stage, it cannot be determined whether the methylene shielding for form I or that for II is the larger. The calculated shielding of ^{13}C for form I is smaller by about 3 ppm than that for form II, so the calculation predicts the existence of a shielding difference (about 3 ppm) between forms I and II. It appears that the calculated shieldings are somewhat exaggerated compared

Table 1 Observed and Calculated ^{13}C Chemical Shifts and Shieldings of an Isolated Polyglycine Chain

with the observed values. Nevertheless, the observed trend that the ^{13}C chemical shift difference for the methylene carbon is very small when compared with that for carbonyl carbon is reproduced qualitatively by the calculation.

3.2 Configuration

Polyacetylene (PA) is the simplest conjugated polyene, and has two configurations (*cis* and *trans*). It has been reported that shielding of ^{13}C in *cis*-PA appears at lower frequency by about 10 ppm than that of *trans*-PA.¹⁰ Calculations of ^{13}C shielding in PAs have been carried out based on the use of CNDO/2 TB MO and INDO/S TB MO. The differences in the isotropic shielding of ^{13}C between *cis*- and *trans*-PAs, calculated using CNDO/2 and the INDO/S TB MO, are about 2.0 and 3.5 ppm, respectively,¹¹ i.e., the results differ by a factor of about 2. As the observed difference is about 10 ppm, both types of calculation somewhat underestimate the real values in this case.

Figure 3 shows the observed¹² and calculated components of the ^{13}C shielding tensors of *cis*- and *trans*-PA. As can be seen, the absolute values of σ_{zz} and σ_{xx} calculated using INDO/S TB MO are smaller by about 40 ppm than those obtained using CNDO/2 TB MO. The value of σ_{yy} calculated using INDO/S TB MO is larger by about 10 ppm than that obtained using CNDO/2 TB MO. Consequently, the separation between the values of σ_{xx} and σ_{yy} calculated using INDO/S TB MO is much larger than that obtained using CNDO/2 TB MO. Furthermore, it has been shown that in going from the calculation using CNDO/2 to that using INDO/S, the values of σ_{zz} and σ_{xx} are changed considerably. The most remarkable difference is the estimation of the π - π overlap integral. Values of σ_{zz} and σ_{xx} are affected by the distribution of π electrons.

The electronic band structure of a PA consists of five valence bands within the framework of the semiempirical method. The highest occupied band has π symmetry. Comparing the electronic band structures calculated using CNDO/2 TB MO with that using INDO/S TB MO, the energies of the three

high-energy bands increase, in particular that of the highest occupied band. As can be seen from Equation (5), σ^p contains a term proportional to the inverse of the excitation energy. The increase in the energies of the three high-energy bands is one of the factors leading to the deshielding of σ_{zz} and σ_{xx} , which implies a lower excitation energy. In fact, the band gaps (the energy difference between the highest occupied and the lowest unoccupied band) for *trans*-PA calculated using CNDO/2 and INDO/S TB MO are about 8.0 and 4.2 eV, respectively. The observed band gap for *trans*-PA is about 1.9 eV. Thus, the contribution of these high-energy bands to σ_{xx} and σ_{zz} is remarkably improved in going from CNDO/2 to INDO/S TB MO.

It is clear from Figure 3 that the reason why the calculated difference in isotropic shielding of ^{13}C between *cis*- and *trans*-PAs is underestimated is that the difference in σ_{yy} cannot be reasonably reproduced. In order to reproduce more reasonably the observed difference in σ_{yy} between *cis*- and *trans*-PAs, it may be necessary to use MOs that can properly describe band structures that have σ symmetry.

Polypyrrole is one of a series of heterocyclic polymers that has attracted much attention because of its characteristic electric and electronic properties. Fundamental structural formulas have been proposed for undoped and doped polypyrroles, where the aromatic form corresponds to the undoped state and the quinoid form to the doped state. From analysis of high-resolution solid state ^{15}N NMR, it is known that the ^{15}N chemical shift for the quinoid form appears to high frequency from that for the aromatic form. In order to obtain information about ^{15}N chemical shifts and electronic band structures of an infinite polypyrrole chain with aromatic or quinoid forms, calculations were carried out using INDO/S TB MO.¹³

As listed in Table 2, the calculated shielding of ^{15}N for the quinoid form appears to high frequency compared with that for the aromatic form. The calculated results agree with observed ones, suggesting that the electronic band structure has been properly estimated. From the calculated electronic band structure, the band gaps for the aromatic and quinoid forms are 5.1 and 2.9 eV, respectively. This result implies that the electrical conductivity of the quinoid form is larger than that of the aromatic form. Therefore, it can be expected that if the amount of the quinoid form is increased, polypyrrole with a higher electric conductivity can be obtained.

3.3 Crystal Structure

The crystal structure in the solid state, which describes how molecules condense, is an important factor when discussing physical properties. The effect of crystal structure on the nuclear shielding can, in principle, be separated from the effect of conformation and configuration to within the limitations of a quantum chemical model.

Experimentally, it is reported that the ^{13}C chemical shifts of the CH_2 carbon for *n*-paraffins, cyclic paraffins,

Figure 3 Observed and calculated components of ^{13}C NMR shielding tensors of *cis*- and *trans*-PAs. The directions of the principal axes are indicated at the bottom

Table 2 Calculated ^{15}N Shieldings and Band Gaps for Aromatic and Quinoid Polypyrrole Models Using INDO/S TB MO

Structure	Calculated shielding σ_{iso} (ppm)	Band gap (eV)
Aromatic	-223.50	5.12
Quinoid	-232.51	2.86

and polyethylene with *trans* zigzag conformations in the orthorhombic and triclinic forms are about 33 and 34 ppm, respectively.^{14,15} As the conformation is the same in each case, the difference of about 1 ppm may be due to a local change in intermolecular interactions resulting from the change of the orthorhombic to the triclinic form. Paraffins can be considered as models for the crystallographic form of the polyethylene. The results of X-ray diffraction studies suggest that the *trans* zigzag plane of any specified chain in the orthorhombic and triclinic forms is, respectively, perpendicular and parallel to that of the neighboring chains. The chemical shift of ^{13}C in polyethylene with a monoclinic form appears at higher frequency by 1.4 ppm compared with that of polyethylene with a orthorhombic form. The orientation of the *trans* zigzag plane in the monoclinic form is very close to that in the triclinic form.¹⁶ Thus, the solid state ^{13}C NMR chemical shift depends on the orientation of the C–C–C plane in the *trans* zigzag chains.

Since the chains lie periodically in space in the solid state, calculations of chemical shifts should be employed that take account of the three-dimensional structure, including interactions between chains. In order to take into account the interchain interaction, a ‘seven-polyethylene-chains model’ has been used to compute the ^{13}C shielding.¹⁷ Figure 4 shows models for polyethylenes with an orthorhombic form and

Figure 4 The ‘seven-polyethylene-chains’ model: (a) orthorhombic form; (b) monoclinic form

Figure 5 The ^{13}C NMR chemical shift difference between the orthorhombic and monoclinic polyethylene chains calculated using the seven-chains model, as functions of the setting angle ψ

a monoclinic form. The setting angle ψ for orthorhombic polyethylene is not clearly determined. Figure 5 shows the ψ dependence of the difference in shielding of ^{13}C between orthorhombic and monoclinic polyethylenes ($\sigma_{\text{orth}} - \sigma_{\text{mono}}$) calculated using INDO/S TB MO. As can be seen, the calculated difference in shielding of ^{13}C between these forms is positive in the case of $\psi = 25^\circ$ – 42° , and negative in the case of $\psi = 20^\circ$ – 25° and $\psi = 42^\circ$ – 55° . The largest difference occurs at $\psi = 35^\circ$. From these results, the angle of $\psi = 25^\circ$ – 42° is good for the setting angle of orthorhombic polyethylene, and can reasonably reproduce the observed data. This result shows that the difference in chemical shift between the orthorhombic and monoclinic forms is caused by the difference in interchain interaction through the electronic band structure.

The effect of crystal structure on the nuclear shielding of *cis*- and *trans*-PA is also relevant. A specified polymer chain is surrounded locally by six neighboring chains in the crystal, and these six chains can be separated into three groups. Each chain group consists of two chains, which are equivalent with respect to the central chain. In order to take interchain interaction into account, the ‘seven-chains model’ has been used to compute the ^{13}C shielding as shown in Figure 6.¹⁸

The calculated values depend on the chain arrangement. The total energies of *cis*- and *trans*-PAs show minima at $\Delta b = -10$ pm, where Δb is the deviation of b from the value determined by X-ray diffraction. A small decrease from the original crystal lattice values determined by X-ray methods leads to energetically stable results in the calculations for both PAs. This arises from the fact that CNDO/2 slightly underestimates the interaction distances, as is already known.¹⁹ However, an extreme decrease in the interchain distance leads to a large instability. Therefore, when comparing *cis*- and *trans*-PAs, it might be appropriate to consider the arrangement with a somewhat shorter distance. With respect to the band gap, the smaller the value of b , the smaller the band gap becomes. The decreases in the lattice parameters in the calculation correspond to the PA system under high pressure, where a shrinkage of the interchain distance occurs. It is therefore suggested that the electric conductivity of PA samples will increase with an increase in pressure. Comparing the isomers, the band gap value of *trans*-PA is smaller than that of *cis*-PA. This explains the experimental observation that *trans*-PA has a higher conductivity than *cis*-PA. The calculated values

Figure 6 Geometrical parameters of *cis*- and *trans*-PA: (a) valence geometries; (b) lattice parameters

are very large for the arrangement given by the original lattice parameters. The arrangement with a small value of b is near to the real form in the crystal. It has been shown experimentally that the lattice parameters a and b for *cis*-PA are larger than those for *trans*-PA (Figure 6); that is, the interchain distance of *cis*-PA is longer than that of *trans*-PA. This may be due to the different shapes of the PA chains. In the comb-like *cis*-PA chains, some of the hydrogen and carbon atoms tend to be very close in interatomic distance, and so they become repulsive (in fact, the nearest-neighbor C-H distance between the chains in *cis*-PA is shorter than that in *trans*-PA in the case using the original geometries). Therefore, the *cis*-PA crystal becomes more stable at the arrangement with the larger lattice parameters than does the *trans*-PA crystal, and these long interchain distances lead to a large band gap and so to a low conductivity for *cis*-PA.

Figure 7 shows the calculated dependence of the shielding of ^{13}C for *cis*- and *trans*-PA on Δb . In the arrangement with

Figure 7 Dependence on b of the calculated isotropic ^{13}C shielding of PA chains in the seven-chains model: $\circ$, *cis*; $\bullet$, *trans*

the original lattice parameters, the calculated values of σ_{iso} do not reproduce the observed large difference between the two isomers. However, in the arrangement with short interchain distances, the calculations agree well with the experiments. With regard to the chemical shift tensors, not only σ_{33} but also the components σ_{11} and σ_{22} decrease as the interchain distance is decreased. The most variable component for a change of the interchain distance is σ_{22} , whose direction is along that of the molecular chain. The effect of the interchain interactions might appear strongly in this direction. At $\Delta b = -100$ pm, the difference in σ_{22} between the isomers agrees quantitatively with the experimental data. From these results, the effect of crystal structure on nuclear shielding can be explained via the electronic structure in addition to the effect of the chain configuration.

1 INTRODUCTION

Most recently, the term ‘*soft materials*’ is frequently used in the field of materials science. *Soft* polymers considered here are classified into soft materials, and contain polymer gels, polymer liquid crystals, vulcanized elastomers, etc., in which molecular motion is much higher compared with solid polymers. Most recently *soft* polymers have attracted attention as useful materials as detailed below.

Polymer gels consist of two components of network polymer chains and solvent. Further, a third component such as a low molecular-weight compound or polymer is often contained in the gels. Polymer gels have attracted considerable attention from the point-of-view of various physical and chemical properties.¹ For example, hydroelectrolyte gels show a dramatic change in volume in response to change in solvent composition, pH, ionic strength and temperature. They contract upon application of an electric field. Further, water-swollen polymer gels can convert chemical energy into mechanical energy. These properties lead to the vitality of polymer research and development of a diversity of interests in polymer gel systems. In order to develop new polymer materials, polymer gel design has been performed on the basis of advanced polymer science and technology. The properties of polymer gels are closely related to their structures and dynamics. From such situations, the establishment of methods for elucidating the structures and dynamics is important for making reliable polymer gel design and developing new advanced polymer gels. In polymer gels, although the mobility of network polymer chains is much higher than solids, it is much lower than solvent and the low-molecular weight molecules. Thus, by taking into account such a difference in molecular motion between the mobile and immobile regions, solid-state

high-resolution NMR proves to be a useful tool to characterize such systems.

On the other hand, liquid crystalline polymers have both positional and orientational orders in the liquid crystalline phase.² The amount of order in a liquid crystal is quite small compared with a crystal. The polymer chain is rapidly rotating around the long axis and diffusing along and perpendicular to the long axis. Such anisotropic structures induce various characteristic properties to be used as materials.

From such a background, the structure and dynamics of polymer gels, liquid crystalline polymers and vulcanized elastomers by solid-state NMR, and the diffusion process of polymer gels by pulse-field-gradient spin-echo (PFGSE) NMR have been widely used in order to make reliable polymer gel and liquid crystalline polymer designs and to develop new advanced polymer gels and liquid crystalline polymers.^{3–5} Details of this work will be described.

2 MICROSCOPIC STRUCTURE AND DYNAMICS OF POLYMER GELS

Polymer gels consist of mobile and immobile regions. For this, conventional solution NMR gives useful information about mobile regions, but sometimes not on the more rigid regions. To obtain structural information on relatively rigid regions, solid-state NMR is required. Then, in order to elucidate structure and dynamics of the immobile and mobile regions in polymer gels, we must use some appropriate NMR methods or must design special methods. In this section, some studies of microscopic structure of polymer gels by ¹H pulse NMR (including use of gradient-field) and high-resolution solid-state ¹³C NMR will be introduced.

2.1 Approach by ¹H Pulse NMR Method

In the pulse NMR experiment, high power radio-frequency (rf) pulses are applied and the free induction decay (FID) of the T_2 component is detected as a time-dependent function that becomes a measure of the mobility.^{5,3} The Fourier transform converts the FID into the corresponding frequency spectrum, in which the chemical shift gives information about chemical structures. On the other hand, the FID contains information about molecular dynamics, and so the experiment with some rf pulses gives T_1 , T_2 and the diffusion coefficient (D).⁶ T_1 and T_2 are closely related with the correlation-time for molecular motion by BPP (Bloembergen–Purcell–Pound) theory when they are governed by dipolar interactions, and D as obtained by pulse NMR under a field gradient provides information about the translational motion.⁷ Therefore, pulse NMR is useful method for the elucidation of molecular dynamics in polymer systems.

2.1.1 Volume Transition of a Poly(*N*-Isopropylacrylamide) Gel

It is known that the volume of a poly(*N*-isopropylacrylamide) (PNIPAM) gel with water as solvent experiences a transition with temperature at about 33 °C.⁸ In order to elucidate molecular motion of water in the gel through the transition temperature (T_{vt}) by temperature variation, the ¹H T_2 has been measured as a function of temperature.⁹

Figure 1 Plots of the ^1H T_2 values of H_2O in neat water (●) and in the PNIPAM gel (○) against temperature at atmospheric pressure

Figure 1 shows plots of the ^1H T_2 values of H_2O in neat water (●) and water in the PNIPAM gel (○), as a function of temperature at atmospheric pressure. The T_2 value of neat water increases as the temperature is linearly increased. This shows that the mobility of water is monotonically increased with increase in temperature in the measurement temperature range. The T_2 of H_2O in the PNIPAM gel increases as the temperature increases up to 33°C . At T_{vt} (33°C), the T_2 value is transitionally decreased. As the temperature is further increased, the T_2 value is transitionally decreased. Such behavior is similar to that of water in aqueous PNIPAM solution as reported previously.¹⁰ During the NMR measurements, the gel shrinks with an increase in temperature and exuded water is physically removed. The degree of swelling Q , which is defined by the ratio of the mass of swollen gel to the mass of dried gel and shows a measure of the size of the network. This implies that the mobility of water in the gel increases with an increase in temperature up to 33°C in spite of much smaller change of the Q value, but decreases transitionally at 33°C due to a large decrease in the Q value and increases again with a further increase in temperature during which the Q value does not change. Such a behavior can be understood by assuming that intermolecular interaction between the network polymer chains above the transition temperature occurs and so the mobility of water molecules is more restricted by the polymer networks than that below the transition temperature.

2.1.2 Gelation of Poly(*N*-isopropylacrylamide) Aqueous Solution

PNIPAM in water undergoes a phase transition from sol to gel at around 32°C .¹¹ ^1H pulse NMR experiments provide useful information about molecular motion of the polymer and solvent in the solution and gel state. The abrupt change in molecular motion for solvent in the gel is caused by the formation of the gel structure at the phase transition temperature and therefore, the change of relaxation times sensitively reflects the change of states.

The ^1H T_2 values for water in 1, 2.5, 5 and 10% w/v PNIPAM/water solutions and for neat water against temperature were measured as a function of temperature.¹⁰ The ^1H T_2 value increases as the temperature is increased up to 30°C , where an increase in T_2 means an increase in molecular motion according to BPP theory.⁷ The ^1H T_2 value of neat water increases linearly with temperature up to 50°C . At the gelation temperature (about 32°C), the ^1H T_2 value in all of the polymer solutions transitionally decreases. As temperature is further increased, the T_2 value increases again. The mobility of water increases with increasing temperature up to 30°C , then decreases transitionally at about 32°C due to the gelation of the system and increases again with a further increase of temperature. This trend is very different from that of neat water. Furthermore, it is seen that the increase in the polymer concentration leads to a decrease in ^1H T_2 for water. The molecular motion of water is restricted by an increase in intermolecular interactions between the polymer chains and water. As the polymer concentration increases up to 5% at the gelation temperature, the magnitude of the decrease for ^1H T_2 value is larger. As the concentration increases further up to 10% w/v, the magnitude of the change in T_2 value for the transition becomes smaller.

The ^1H T_1 value of water molecules in 5% w/v PNIPAM/water solution was measured as a function of temperature. The ^1H T_1 value slowly increases as does the ^1H T_2 mentioned above as the temperature is increased. At the gelation temperature, the T_1 value transitionally decreases. As the temperature is further increased, the ^1H T_1 value slowly increases. This behavior is very similar to that for T_2 . As seen from the observed ^1H T_1 and T_2 behaviors, the water molecules are in the fast motion region ($\omega\tau_c \ll 1$, where ω is the resonance frequency). At 1, 2.5 and 10% w/v solutions, similar results were obtained. Therefore, the ^1H T_1 and T_2 values for water in the PNIPAM/water system are very sensitive to the phase transition and provide dynamic information.

In PNIPAM/deuterated water solution, the ^1H T_2 signal is composed mainly of two components, a long T_2 component corresponding to the side chains and extremely short T_2 component corresponding to the main chain. The T_2 value for the main chain and side chains of PNIPAM in 10% w/v PNIPAM/deuterated water solution were determined as a function of temperature. For the main chain, at temperatures from 10 to 30°C , the T_2 value is almost constant, but at the gelation temperature (32°C) it decreases transitionally, and at temperatures of 40 – 50°C it returns to being constant. This indicates that at the gelation temperature, the molecular motion of the main chain is greatly restricted. On the other hand, for the side chains, at temperatures from 10 to 30°C the T_2 value remains almost constant, increases transitionally at the gelation temperature, and at temperatures from 40 to 50°C it becomes a constant again. This is evidence that the molecular motion of the side chains increases transitionally at the gelation temperature.

By evaporating water slowly from PNIPAM aqueous solution, a PNIPAM gel is obtained. The ^1H T_2 behavior of water for this gel is very similar to that for PNIPAM aqueous solution. This shows that temperature changes of structure and dynamics for both of these systems up to 32°C are very similar to each other.¹⁰ Further insight into structural and dynamic changes by changing temperature has been studied by high-resolution solid-state ^{13}C NMR technique.

2.1.3 Structure and Dynamics of Poly(vinyl alcohol) Gel

Amorphous-poly(vinyl alcohol) (PVA) gel prepared by repeating freeze-thaw cycles from its aqueous solution is one of the physical gels.¹² A ^1H spin echo signal of PVA gel measured is composed of three components such as a long T_2 component corresponding to the mobile region (C), a short T_2 component corresponding to the immobile region (A) and an intermediate T_2 component corresponding to the interfacial region (B), which exists between the mobile and immobile regions.¹³ It can be said that the mobile region (C) comes from the non-crosslinked region, the immobile region (A) comes from the crosslinked region and the interfacial region (B) comes from the vicinity of the crosslinked region in the gel. With an increase in the polymer concentration, ^1H T_2 of three regions are slowly decreased. This means that the molecular motion is restrained, as the polymer concentration is increased. The fractions of the corresponding three regions were determined as a function of polymer concentration. The fractions of the mobile and immobile regions are largely decreased and increased with an increase in the polymer concentration, respectively. The fraction of the intermediate region over a wide range of polymer concentrations is very small.

2.1.4 Gelation of Poly(vinyl alcohol)/Water System Under High Pressure

As mentioned above, PVA aqueous solution forms a gel by undergoing freeze-thaw cycles. The gelation is induced by network formation, and at the initial step of the gelation phase separation occurs by forming polymer-aggregation region and polymer-unaggregation regions. It has been suggested that the cause of the gel formation in PVA aqueous solution is due to the formation of intermolecular hydrogen bonds.^{14,15}

The use of variable pressure is very effective in overcoming the limited interpretability of the results obtained at atmospheric pressure. Additionally, a change in pressure is expected to provide another dimension in the investigation of aqueous PVA solution and gel because volume changes by the application of pressure lead to reduction of intermolecular distance and to a major effect on molecular motion in the system compared with experiments conducted at atmospheric pressure. As viewed from high pressure NMR experiments, it can provide more useful information about intramolecular dynamics, structures of liquids, molecular conformations and intermolecular interactions through the observation of some NMR parameters such as chemical shift, T_1 , T_2 and dipolar splitting.^{13,16} From such a situation, it can be expected that more detailed information about the dynamical behavior of PVA/water system is obtained by the application of pressure. Therefore, the dynamical behavior of PVA aqueous solution and gel through the observation of ^1H T_2 values is elucidated as a function of pressure from 1 to 500 kg cm⁻² by using high pressure ^1H pulse NMR.¹⁷

The degree of polymerization of amorphous PVA used in this experiment was 300. PVA was dissolved in D₂O at 90 °C to observe the ^1H signal from the polymer. To remove the ^1H signal from HDO, which came from chemical exchange between hydroxyl proton and deuterium in PVA and D₂O, the following procedure was performed. By adding PVA/D₂O solution into excess acetonitrile, PVA substituted hydroxyl proton by deuterium (*d*-PVA) was precipitated.

The precipitated *d*-PVA was dried by a vacuum pump. The obtained *d*-PVA was dissolved in D₂O again. This procedure was repeated three times. Deuterated PVA samples were dissolved in D₂O at 90 °C. The concentration was 10% (w/w). The solution was cooled to 25 °C and kept for 10 days (sample I). PVA chains in aqueous solution aggregate slightly by such a cooling process. For this, the ^1H T_2 value for the PVA solution was measured as a function of the elapsed time during the cooling process. It is obvious that the change of the ^1H T_2 with the elapsed time is much smaller compared with that under pressure. PVA gel was prepared from PVA/D₂O solution by repeating freeze-thaw cycles 3 times (frozen and kept at -15 °C for 3 hours, and melted and kept at 25 °C for 2 hours) (sample II).

Pulse ^1H NMR measurements were carried out at 20 MHz. ^1H T_2 was determined by the CPMG (Carr–Purcell–Meiboom–Gill) method to obtain information about the molecular motion of PVA chain in the solution state, and was determined by the solid echo pulse sequence to obtain information about the molecular motion of the immobile component in the gel state. The T_2 decay for the PVA solution was analyzed as a sum of Lorentzian-type decays and for the PVA gel was analyzed as sum of Gaussian-type decays using the nonlinear least-squares method.

In high pressure experiments, the sample cell was made from a Pyrex glass capillary tube with an outside diameter of 5.0 mm and an inside diameter of 2.6 mm. The cracks on the surface of the outside and inside of the capillary tube were etched by aqueous HF solution. The capillary was glued to a nonmagnetic stainless steel tube using epoxy resin. The pressure can be changed from 1 to 500 kg cm⁻² with no failure of the system.

From the ^1H CPMG experiments on PVA aqueous solution at room temperature, the T_2 signal is mainly composed of two components. The PVA chains in aqueous solution aggregate partly by the cooling process when the solution is prepared. From such a situation, the long T_2 component comes from the mobile region, which is assigned to non-aggregated PVA chains. The short T_2 component comes from the immobile region, which is assigned to aggregated PVA chains in the solution state. The ^1H FID signals of PVA/D₂O solution are shown as a function of pressure in Figure 2. The ^1H FID signals of PVA chains at pressures from 1 to 100 kg cm⁻² slowly decay, and at pressures over 200 kg cm⁻² the variation of decay increases. The ^1H T_2 values for PVA/D₂O solution were determined as a function of temperature. The ^1H T_2 value for the immobile region is almost a constant to be about 25 ms at pressures from 1 to 500 kg cm⁻². On the other hand, the ^1H T_2 value for the mobile region is changed by pressure. The ^1H T_2 value is lowered from ca. 650 to 600 ms in the pressure range from 1 to 100 kg cm⁻², and again decreases from ca. 600 to ca. 100 ms in the pressure range from 100 to 200 kg cm⁻². At pressures over 200 kg cm⁻², the ^1H T_2 values for the long T_2 component are constant at about 100 ms. These experimental results indicate that the molecular motion of PVA chains in the aggregated region is not changed by varying pressure up to 500 kg cm⁻², but the molecular motion in the non-aggregated region is affected by pressure in the pressure range over 200 kg cm⁻². The ^1H T_2 value for mobile component is about 320 ms and the ^1H T_2 value for mobile component at 1 kg cm⁻² decreases by applying pressure. The long T_2 component disappears in the pressure range over 200 kg cm⁻².

Figure 2 Pressure dependence of ^1H T_2 signal of PVA/D₂O solution obtained by the CPMG method

and the fraction of the short T_2 component increases up to 200 kg cm^{-2} . In the pressure range over 200 kg cm^{-2} , the short T_2 component occupies the whole fraction. From these results, it can be said that the molecular motion of PVA chains in non-aggregated region is restricted by applying pressure up to 500 kg cm^{-2} , and the process of gelation is induced. Finally, it can be said that high-pressure ^1H pulse NMR gives useful information about the dynamics of PVA chains in aqueous solution state and in gel state.

2.1.5 Structure and Dynamics of (Ethylene-Vinyl Alcohol) Copolymer Gels

Ethylene-vinyl alcohol (EVOH) copolymer gel can be prepared by repeating freeze-thaw cycles from its aqueous solution similarly to the preparation of the PVA gel. The ^1H T_2 signal of EVOH gel with a relatively high ethylene content of 32% as obtained by ^1H solid echo method was observed.¹⁸ The ^1H T_2 value is determined from the slope of the plot of $\ln M$ against t^2 , where M is the amplitude of the spin echo signal and the T_2 signal is assumed to be a Gaussian decay in the spectral analysis. According to the BPP theory for NMR relaxation, T_2 decreases continuously as the correlation time τ_c in molecular motion is increased.⁷ This means that shorter T_2 corresponds to slower molecular motion. Thus, T_2 can give dynamic information about the gels through the BPP theory. The ^1H T_2 curve is composed of three kinds of the components; the short T_2 component

corresponding to the immobile region (A), the intermediate T_2 component corresponding to the interfacial region (B), which exists between the mobile and immobile regions, and the long T_2 component corresponding to the mobile region (C). By aid of the computer-fitting, the ^1H T_2 value was obtained from the T_2 signal with experimental error of $\pm 5\%$. The result is the same as that of PVA gel.¹³ It can be said that the short T_2 component corresponding to the immobile region comes from the crosslinked region in the EVOH gels, the long T_2 component corresponding to the mobile region comes from the non-crosslinked region, the intermediate T_2 component with the intermediate mobility comes from the vicinity of the crosslinked region.

The ^1H T_2 values determined for the individual regions were plotted against the ethylene content. It is found that the ^1H T_2 values for the immobile, mobile and intermediate regions are gradually decreased with an increase in ethylene content. The increase of the ethylene content in EVOH samples in the gel state leads to reduction in molecular motion for the individual regions.

The fraction of each of the immobile, mobile and intermediate regions with different molecular motion were determined as a function of ethylene content. In the range of ethylene content less than 55%, the fractions of three kinds of regions with different mobilities are almost independent of ethylene content. In the ethylene content range greater than 55%, the fractions of the mobile region are rapidly decreased with an increase in ethylene content. On the other hand, the fractions

of the intermediate and immobile regions are largely increased with an increase in ethylene content. Their fractions are similar in value. This means that the fraction of the crosslinked region as formed by an addition of hydrophobic interaction between the ethylene parts to hydrogen bonds between the vinyl alcohol units is increased with an increase in ethylene content. From such a situation, the molecular motion for all of the three regions are more restrained with an increase in ethylene content.

2.1.6 Structure and Dynamics of Swollen Polymer Networks

The structural and dynamic characterization of swollen polymer networks has been one of the important research programs in polymer science. Samulski, et al. have elucidated the effect of orientation on residual quadrupolar splitting of deuterated solvents in swollen strained polyisoprene by ^2H NMR.⁵⁷ The quadrupolar splitting depends linearly on $\lambda^2 - \lambda^{-1}$ over a large range of the extension ratios (λ) and the degree of swellings. A phenomenological description based on a lattice model of the deformed, swollen network, which induces short-range nematic-like interactions successfully accounts for the observations. Also, the structural characterization of the other swollen networked polymers have been studied by ^2H NMR.^{58–60}

2.2 Approach by High-Resolution Solid-State ^{13}C NMR

It is well known that ^{13}C CP/MAS (cross polarization/magic angle spinning) NMR method obtains high-resolution solid-state NMR spectra of solid polymers and enhances the peak intensity of carbons in the immobile region.^{3,19–21} The CP efficiency is relatively high for carbons in rigid solid polymers. Polymer gels and polymers in the liquid crystalline state are relatively mobile. For this reason, care must be exercised to obtain ^{13}C CP/MAS NMR spectra because the ^{13}C signals of carbons in the mobile region may not appear due to the large reduction of the CP efficiency. It is often convenient to use MAS with strong ^1H decoupling, which leads to NOE (Nuclear Overhauser Effect), and without CP for obtaining the ^{13}C signals of carbons in the mobile state, for example, the PST (pulse saturation transfer)/MAS is often used, in which ^1H decoupling is carried out by using a number of pulses.²² MAS removes effectively weak dipolar coupling of carbons in the immobile state. In the case of polymer gels there exist mobile and immobile regions. For this, ^{13}C CP/MAS and PST/MAS methods are often used to get useful information about both regions. This leads to reasonable structural characterization of polymer gels.

If a conventional NMR rotor is used under high speed rotation (about 4 kHz), polymer gels and polymer liquid crystals come out of a conventionally sealed NMR rotor due to high speed rotation. From such a situation, it is convenient to use an NMR rotor sealed with an O-ring rubber, the use of which prevents loss of samples.¹⁴

2.2.1 Structural Characterization of Poly(Vinyl Alcohol) Gel

As mentioned above, amorphous-PVA gel is prepared by repeating freeze-thaw cycles from its aqueous solution. At the beginning of the gelation of the PVA aqueous solution, phase separation into polymer-rich and polymer-poor regions occurs

with a decrease in temperature. It is suggested that the gel formation is due to the formation of intermolecular hydrogen bonds.¹⁴ The structure and the amount of hydrogen bonds may play an important role for properties of PVA gel, and high-resolution solid-state ^{13}C NMR gives useful information about them.^{14,15} Figure 3 shows ^{13}C NMR spectra for PVA in the solution (a), gel (b–d) and solid (e) states as measured by solution and solid-state NMR. In conventional solution ^{13}C NMR spectrum for PVA gel shown in Figure 3(b), the ^{13}C signal for the CH carbon splits into three peaks assigned to mm, mr and rr triads. The signals for the CH and CH_2 carbons become broader as compared with those for PVA solution (Figure 3(a)). This is caused by the increase in dipole–dipole interactions due to a decrease in molecular motion. The ^{13}C PST/MAS NMR spectrum of the PVA gel shown in Figure 3(c) is similar to the solution NMR spectrum of Figure 3(b). However, the resolution of spectrum (c) is better than that of spectrum (b), because of a MAS and a high-power proton decoupling. NOE enhancement is used to obtain more intense ^{13}C signal using PST method.²² The PST method effectively enhances peak intensity for the mobile regions in samples as compared with CP and vice versa. This means that the mobile region in the PVA gel is observed in both spectra (b) and (c). The ^{13}C signal for the CH carbon of the solid PVA has three-split broad peaks in the ^{13}C CP/MAS NMR spectrum

Figure 3 ^{13}C NMR spectra for the PVA in the solution, gel and solid states as measured by solution and solid-state NMR methods. For solution NMR method: PVA/ D_2O solution (a) and PVA gel (b); for solid-state NMR method: PVA gel by PST/MAS (c) and CP/MAS (d), and solid PVA by CP/MAS (e)

as shown in Figure 3(e). Such a splitting is explained by the number of intramolecular hydrogen bonds formed among neighboring hydroxyl groups. Assuming that the ^{13}C chemical shift value for the CH carbon shifts to downfield by 6 ppm per one intermolecular or intramolecular hydrogen bond, the most deshielded peak (peak I) can be assigned to the CH carbon with two hydrogen bonds, the central peak (peak II) to the CH carbon with one hydrogen bond and the most shielded peak (peak III) to the CH carbon with no hydrogen bonds, respectively.²³ In the ^{13}C CP/MAS spectrum for the PVA gel as shown in Figure 3(d), the CH signal is composed of the three splitting peaks corresponding to the triad tacticity and the broad peaks as found in the solid PVA. This means that in this case both of the immobile and mobile regions of the PVA gel are observed by CP/MAS.

Figure 4 shows ^{13}C CP/MAS NMR spectra of the PVA gels with different polymer concentrations.¹⁴ The polymer concentrations of samples (a), (b), (c) and (d) are 9.1, 11.8, 13.8 and 35.0% (w/w), respectively. The intensities of the three-split peaks due to stereochemical configurations decrease and those of peaks I, II and III increase with a decrease in water fraction in the gel. The three peaks due to stereochemical configurations completely disappear in sample (d). The schematic crosslinked structure of PVA gel formed by intermolecular and intramolecular hydrogen bonds can be inferred from these spectra. The increase in the fraction of the immobile region and the formation of hydrogen bonds are promoted by the increase in the polymer concentration of the gel.

In order to clarify the dynamics of PVA gel, ^{13}C T_1 measurements were carried out.¹² The ^{13}C T_1 values for the mobile region in a PVA gel were determined by the inversion-recovery method combined with the PST/MAS technique and the immobile region was also determined using CP/MAS combined with Torchia's pulse sequence.⁵⁴ The T_1 values for the triads are

Figure 4 ^{13}C CP/MAS NMR spectra for PVA gels with different polymer concentrations. The polymer concentrations are (a) 9.1, (b) 11.8, (c) 13.8 and (d) 35.0% (w/w), respectively

smaller than those for peaks II and III. The immobile region corresponds to the CH carbons in the crosslinked regions formed by intermolecular and intramolecular hydrogen bonds in the gel, and the mobile ones to the regions away from the crosslinked regions that undergo fast molecular motion in the gel. The mobility of the network polymer in the PVA gel is restrained by hydrogen bonds and especially that of the crosslinked region is very low.

2.2.2 Gelation Mechanism of Poly(Vinyl Alcohol) in Aqueous Solution

PVA in aqueous solution forms a gel by undergoing freeze-thaw cycles. We have studied the structure and dynamics of PVA gels that were prepared using PVA samples with different microtacticity at some polymer concentrations under atmospheric pressure and high pressure by high-resolution solid-state ^{13}C NMR and ^1H pulse NMR.^{14,15,17} From these studies, we have demonstrated that the crosslinked region is formed by the formation of intermolecular hydrogen bonds. From such a situation, in this work we aim to measure high-resolution solid-state ^{13}C NMR spectra during the freeze-thaw cycles, and to elucidate the mechanism of gelation process for PVA in aqueous solution.

The degree of polymerization and the degree of saponification of amorphous PVA were 1700 and 99.9%, respectively. The PVA sample was dissolved into water at 120 °C using an autoclave. The polymer concentration was 10% (g dl⁻¹). The obtained PVA aqueous solution was cooled to room temperature and was contained in a cylindrical rotor with a rubber O-ring to prevent loss of water during the NMR measurements. Prior to NMR measurement, it was kept at room temperature for one month to reach a stable state.

^{13}C CP/MAS NMR spectra of PVA/water system during the freeze-thaw cycles are shown in Figure 5.²⁴ There are no signals in the ^{13}C CP/MAS NMR spectrum of aqueous PVA solution at 40 °C, because in the solution state the PVA chains are undergoing much faster molecular motion compared with a frequency of ^1H decoupling to be ca. 60 kHz used in this experiment, and so the CP efficiency is quite reduced. In the ^{13}C CP/MAS NMR spectrum of the PVA/water system in the freezing state at -30 °C, three peaks I, II and III for the CH signal, which come from the formation of hydrogen bonds as reported previously appear clearly.¹⁴ Peak I was assigned to carbons with two intermolecular or intramolecular hydrogen bonds, peak II to those with one intermolecular or intramolecular hydrogen bond, and peak III with no hydrogen bond. From this spectrum, it can be seen that some hydroxyl groups form hydrogen bonds at -30 °C as in the PVA gel. If the temperature is increased from -30 to 40 °C again, peak II at 71 ppm becomes broad and the three splitting peaks due to the triad configurations (mm, mr and rr) appear. This result shows that the molecular motion of PVA chains is decreased compared with that in the original solution state due to the formation of hydrogen bonds, and so the CP efficiency was enhanced. This means that the freeze-thaw process induces gel formation. In ^{13}C CP/MAS NMR spectrum of the PVA/water system in the 2nd frozen state, the three CH peaks are observed as clearly as the case in the 1st frozen state. The ^{13}C CP/MAS NMR spectra in the 3rd and 4th frozen states are almost identical. On the other hand, in the ^{13}C CP/MAS NMR spectrum of the PVA/water system in the thawing state

Figure 5 ^{13}C CP/MAS NMR spectra for PVA/water system under the freeze-thaw cycles

at 40°C , the intensity of peak II is gradually increased with an increase in the number of freeze-thaw cycles. In the 4th thawing state, peak II clearly appeared. This shows that the amount of hydrogen bonds in the course of the formation of the PVA gel is increased by repeating the freeze-thaw cycles.

These experimental results mean that the repeating of freeze-thaw cycles induces the gelation of the PVA/water system.

From these experiments, the mechanism of gelation for the PVA/water system was proposed as follows: in the solution state, there are no strong intermolecular hydrogen bonds and so the corresponding CH peak cannot be obtained using ^{13}C CP/MAS NMR method. In the frozen state, water is frozen and the PVA chains aggregate to form the polymer-rich domain. In the polymer-rich region, strong intermolecular hydrogen bonds may be formed and the corresponding CH peaks are clearly observed by ^{13}C CP/MAS NMR. By repeating the freeze-thaw cycles, the fraction of the polymer-rich regions is increased, and then the crosslinked region is formed, which consists of strong hydrogen bonds. Therefore, it can be said that the process of repeating the freeze-thaw cycles induce intermolecular hydrogen bonds and so is essential for the gelation of the PVA/water system.

2.2.3 Structure and Dynamics of Poly(γ -Methyl L-Glutamate) Gel

The properties of the polymer gels swollen in organic solvents are different from those of hydro-swollen gels. Crosslinked poly(γ -methyl L-glutamate) (PMLG) is prepared by the ester-amide exchange reaction using diaminododecane as a cross-linker and is swollen in trifluoroacetic acid (TFA) and CHCl_3 . The PMLG gel was studied by using high-resolution solid-state ^{13}C NMR spectroscopy.⁵⁵ A typical ^{13}C PST/MAS NMR spectrum of PMLG gel swollen in CHCl_3 is shown in Figure 6. The amide and ester carbonyl carbons of PMLG appear at 176.2 and 173.5 ppm, respectively. The C_α , OCH_3 , C_γ and C_β carbons appear at 57.6, 52.3, 31.3, and 26.1 ppm, respectively. The peak intensities of the side chain carbons is more intense than that of the main chain carbons.

Figure 6 ^{13}C PST/MAS NMR spectrum of PMLG gel swollen in CHCl_3

This means that the side chains are undergoing faster molecular motion compared with the main chain.

The ^{13}C chemical shifts of the individual carbons of PMLG gel are changed as a function of the TFA content (f_{TFA}) in a mixture of CHCl_3 and TFA. In the PMLG gel with CHCl_3 , the ^{13}C chemical shift values of the main chain amide $\text{C}=\text{O}$ and $\text{C}\alpha$ carbons are 176.2 and 57.6 ppm, respectively. The PMLG chain part of the crosslinked network takes the α -helix conformation as determined by reference data²⁵ of solid polypeptides at about 176 and 57 ppm. The amide $\text{C}=\text{O}$ and $\text{C}\alpha$ ^{13}C chemical shifts change transitionally from 176.5 and 57.6 ppm to 174.0 and 54.4 ppm, respectively, and so move upfield with an increase in TFA content. Such a transitional upfield shift shows that the main chain conformation of the PMLG network changes from the α -helix to the random coil form. The midpoint of the transition is at about $f_{\text{TFA}} = 0.15$. On the other hand, it is shown that in the side chain carbons the ester $\text{C}=\text{O}$ carbon moves downfield at the transition point, but the chemical shifts of the other carbons do not change clearly. The chemical shift of the main chain arises from the conformational change due to the formation of intramolecular hydrogen bond between the $\text{C}=\text{O}$ and $\text{N}-\text{H}$ in the main chain. The main chain chemical shift is considered to be very sensitive to the helix-coil transition. The large shift difference of the ester carbonyl carbons is due to the interaction with TFA. The ^{13}C chemical shifts of the other side chain carbons also show small changes at $f_{\text{TFA}} = 0.15$.

The degree of swelling for the PMLG gel is a function of f_{TFA} . The degree of swelling is transitionally decreased at $0-0.05 f_{\text{TFA}}$, is constant at $0.05-0.2 f_{\text{TFA}}$ and is gradually increased at $f_{\text{TFA}} > 0.2$. In the range $0.05-0.2$, the fraction of the random coil form is increased gradually with an increase in f_{TFA} and the degree of swelling is constant. The TFA content dependence of the ^{13}C T_1 of amide $\text{C}=\text{O}$ and ester $\text{C}=\text{O}$ carbons was observed at 20 and 40 °C. As the temperature decreases from 40 to 20 °C, the ^{13}C T_1 for the amide $\text{C}=\text{O}$ carbon increases and that of the ester $\text{C}=\text{O}$ carbon decreases. The molecular motion of the amide $\text{C}=\text{O}$ carbon is in the slow motion region ($\omega\tau_c \gg 1$, where ω is the resonance frequency) and that of the ester $\text{C}=\text{O}$ carbon is in the fast motion region ($\omega\tau_c \ll 1$) according to the BPP theory. The decrease in ^{13}C T_1 of the ester $\text{C}=\text{O}$ carbon in f_{TFA} from 0 to 0.05 shows that the decrease in molecular motion of side chain caused by a rapid shrinkage of the gel. In the range $f_{\text{TFA}} = 0.05-0.20$, ^{13}C T_1 of the amide $\text{C}=\text{O}$ carbon decreases with an increase in TFA content. This means that the molecular motion of main chains is increased in going from the α -helix to the random coil in the constant degree of swelling. On the other hand, the molecular motion of the side chains is not so affected by the helix-coil transition.

2.2.4 Structural and Dynamic Characterization of EVOH Gels

In the CP method, enhancement of the ^{13}C magnetization is effective for the relatively immobile solid-like region, but is greatly reduced for the mobile region in gels. For this, it is expected that ^{13}C CP/MAS NMR gives us dynamic information about gels in an addition to structural information. ^{13}C CP/MAS NMR spectra of EVOH gel samples were measured over a wide range of ethylene contents from 5 to 74% at room temperature.¹⁸ Only the intense background

signal in the ^{13}C CP/MAS spectra of EVOH gels with low ethylene contents from 5 to 48% appears. This results from the following reasons. At the measurement temperature, the gels are very soft, so the mobility of EVOH network chains becomes high. This leads to a large reduction of the CP efficiency. Thus, the background signal that comes from the polymer materials used in an NMR probe appears intensely in the spectrum. This was recognized from the CP/MAS experiment using an NMR rotor containing no sample. The ^{13}C CP/MAS spectra of EVOH samples with high ethylene content of 55 and 74% were obtained with a reasonable signal-to-noise ratio. It is found that the spectral patterns for the CH carbon of the V units and for the CH_2 carbon of the E and V units are greatly changed by varying the ethylene content. In order to obtain the sufficient CP efficiency for the immobile component of EVOH gels with low ethylene content, ^{13}C CP/MAS NMR spectra of EVOH gel with the ethylene content of 5% were measured with repetition time of 5 s by changing of the contact time in the range from 100 to 2000 μs . At long contact time the noncrystalline region that is undergoing slow molecular motion can be often observed.

The ^{13}C PST/MAS NMR spectrum of EVOH gel with ethylene content of 5% was shown in Figure 7(b). This spectrum is similar to solution-state ^{13}C NMR spectrum of EVOH, like the case of PVA gel.^{14,15} In the spectrum, the mm, mr and rr triad peaks for the CH carbon (in the 65–69 ppm region), and the m and r diad peaks for the CH_2 carbon (in the 45–48 ppm region) of V units in EVOH appear clearly. It can be said that the V units in the highly mobile region are observed by the PST/MAS NMR. On the other hand, ^{13}C CP/MAS NMR spectrum of its gel was measured under different conditions of the contact time of 1000 μs , the repetition time of 3 s and the accumulation number of 150 000 from the measurement condition used for the observed ^{13}C CP/MAS NMR spectra (see Figure 7(a)). In this spectrum, peaks I, II and III for the CH carbon of V units, which come from the immobile region, and the mr peak of the triad peaks (as appeared in the 65–69 ppm region) for the CH carbon, which comes from the mobile region appears clearly as shown in Figure 7(a). On the other hand, EVOH gel samples with higher ethylene-content become very hard, and thus ^{13}C CP/MAS NMR spectra of EVOH gels with the ethylene contents of 55 and 74% appear more clearly with a reasonable signal-to-noise ratio even at room temperature because the gels are solid-like, so their molecular motion is greatly restrained. This does not conflict with the pulse ^1H NMR results, in which the ^1H T_2 value of EVOH gels is decreased with ethylene content and the fractions of the mobile and intermediate regions (corresponding to the crosslinked and non-crosslinked regions, respectively) in EVOH gels with ethylene content larger than 55% are increased.

Next, we are concerned with temperature-variable ^{13}C CP/MAS NMR spectra of EVOH gels to obtain further dynamic information on the gels. ^{13}C CP/MAS NMR spectra of EVOH gels with ethylene content of 32% at 0 and 23 °C are shown in Figure 8. The ^{13}C CP/MAS NMR spectrum at 23 °C has very low signal-to-noise ratio and thus the intense background signal appears as a whole as shown in Figure 8(a). This means that the CP efficiency of the gels becomes insufficient by undergoing fast molecular motion at 23 °C, where these gel samples are very soft and thus mobility is high. As temperature is decreased, the individual peaks

Figure 7 67.8 MHz ^{13}C NMR spectra of EVOH gel with ethylene content of 5% at room temperature. (a) CP/MAS NMR spectrum and (b) PST/MAS NMR spectrum

in the spectrum (a) at 0°C appear more clearly compared with the spectrum (b) at 23°C . This is due to an increase in the CP efficiency by reduction of molecular motion at low temperature. The three peaks I, II and III for the CH carbon of the V units appear like the ^{13}C CP/MAS NMR spectra of solid EVOH samples.²⁹ Further, the EVOH copolymer gel prepared by using a mixture of DMSO and water as solvent is relatively harder compared with one prepared by using DMSO as solvent. This is because the intermolecular affinity between EVOH and mixture solvent of DMSO and water becomes much lower compared with that between EVOH and DMSO solvent, and then the hydrophobic and/or hydrophilic interactions between polymer chains are enhanced.

Thus, the EVOH copolymer with the ethylene content of 32% as prepared by using a mixture of DMSO and water as solvent becomes relatively solid-like. This leads to the ^{13}C CP/MAS NMR spectrum of the EVOH gel being well resolved with a reasonable signal-to-noise ratio, similar to solid EVOH.^{26–29} All peaks in these spectra can be assigned in the same way as already assigned in PVA gel¹⁴ and solid EVOH²⁹ as below.^{14,29}

Next, we are concerned with the spectral analysis. The spectral assignment was made according to the previous assignments on solid EVOH samples.²⁹ First, the assignment of the ^{13}C peaks of the CH carbon was made. The assignment of three peaks I, II and III of the CH carbon in EVOH gel with low ethylene content, which appeared at about 77, 71 and

Figure 8 67.8 MHz ^{13}C CP/MAS NMR spectra of EVOH gel with ethylene content of 32% at 0°C (a) and 23°C (b)

65 ppm, respectively, can be made according to the assignment of the CH peaks in PVA gel.¹⁴ Peak I comes from the formation of two intramolecular or intermolecular hydrogen-bonds, peak II from the formation of one intramolecular or intermolecular hydrogen-bond, and peak III from no hydrogen bond. On the other hand, in EVOH gel samples with high ethylene content, the ^{13}C chemical shift positions of peaks I and II are different from those in EVOH gel samples with low ethylene content. This is due to appearance of new configurational arrangements by the large amount of the ethylene units in the copolymers. From such a situation, according to the previous assignment we assign peak I to CH carbon of the V unit in EVE sequence as the major contribution in addition to two intramolecular or intermolecular hydrogen-bonded CH carbon of the V units as the minor contribution, and peak II from one intramolecular or intermolecular hydrogen bonded CH carbon of the central V unit in VVV sequences as the minor contribution.²⁹ Further, by analyzing the partially-relaxed spectra of EVOH gel (with the ethylene content of 5%) by using the Torchia method, it was found that each of three CH peaks I, II and III in EVOH gel remains even at longer delay time (≈ 15000 ms). This arises from the fact that peaks I, II and III in EVOH gel are frozen in molecular motion on the NMR timescale, because these three peaks comes from the crosslinking region in the gel. From the present results and the previous results in the sample of low ethylene content, it is concluded that the formation of hydrogen bonds between vinyl alcohol parts of EVOH contributes to gel formation.^{16,17}

Further, we are concerned with the peak assignment of the CH_2 carbon in EVOH gel with high ethylene content. The CH_2 peaks at 30 and 33 ppm come from the asterisked central CH_2 carbons in both of the $-\text{CH}_2-\text{CH}_2-\text{CH}_2^*-\text{CH}_2-\text{CH}_2-$

unit and $-\text{CH}_2-\text{CH}_2-\text{CH}_2^*-\text{CH}_2-\text{CH}_2-$ unit with and without fast exchange between the *trans* and *gauche* conformations, respectively. The CH_2 peak at 30 ppm decays more rapidly than the CH_2 peak at 33 ppm. This arises from the fact that the CH_2 carbons of the ethylene units with the *trans* zigzag conformation in the crystalline region, which appear at 33 ppm, are frozen on the NMR timescale. On the other hand, the CH_2 carbons in the non-crystalline region, which appear at 30 ppm, are undergoing fast exchange between the *trans* and *gauche* conformations at room temperature.^{30,31} In this case, in EVOH samples with high ethylene content, the gel may be formed in the crystalline region by hydrophobic interactions between the ethylene units of EVOH.

2.2.5 Structural Characterization of Poly(Methacrylic Acid) Gel

The structural and dynamic characterization of poly(methacrylic acid) gel with water as a function of degree of crosslinking was carried out through the observation of high-resolution solid-state ^{13}C NMR spectra by using ^{13}C PST/MAS NMR.⁴¹ ^{13}C PST/MAS NMR spectra of PMAA gels with $Q = 3.4, 21.7$ and 105.8 are shown in Figure 9.⁵⁶ It is seen that high-resolution spectra are obtained. This indicates that the efficiency of MAS to obtain high resolution spectrum is very high for polymer gel systems. The peaks of the PMAA gel can be assigned to the $\text{C}=\text{O}$, CH_2 , quaternary C, and CH_3 carbons from downfield. Each of the $\text{C}=\text{O}$ and CH_3 carbon signals is split into three peaks due to the triad configurations of PMAA. These peaks are designated by the $\text{C}=\text{O}$ (rr:182.5 ppm), $\text{C}=\text{O}$ (mr:181.5 ppm), $\text{C}=\text{O}$ (mm:180.8 ppm), CH_3 (mm:22.3 ppm), CH_3 (mr:19.8 ppm)

Figure 9 ^{13}C PST/MAS spectra of PMAA gels with $Q = 105.8$ (a), 21.7 (b) and 3.4 (c) at 300 K

and CH_3 (mm:18.2 ppm). The peak intensity ratio of these triad signals corresponds to the triad fraction. From the CH_3 signals, the triad fraction is evaluated as rr:mr:mm = 67.4 : 27.1 : 5.5%. The ^{13}C chemical shift values for the PMAA gels are independent of Q . This means that there is no specific effect on the ^{13}C chemical shift by changing Q .

From the ^{13}C T_1 measurements, it was found that molecular motion of the side chain carbons is in the extremely narrowing region in the BPP theory and that of the main chain carbons is in the slow motion region, and an increase in the degree of crosslinking in the PMAA gel leads to restraint in the segmental motion of the network polymer.

2.2.6 Structural and Dynamic Characterization of Poly(L-Glutamates) with *N*-Alkyl Side Chains in the Thermotropic Liquid Crystalline State

It is known that in a series of α -helical poly(L-glutamates) with *n*-alkyl side chains of various lengths, *n*-alkyl side chains longer than $n = 10$ form a crystalline phase composed of paraffin-like crystallites together with an α -helical main chain packing into a characteristic layer structure. The polymers form thermotropic liquid crystals by the melting of the side chain crystallites. The structural and dynamic behavior of the polymers over a wide range of temperatures in going from the solid state to the thermotropic liquid crystalline state has been elucidated by variable temperature ^{13}C CP/MAS NMR.^{33,34} It has been demonstrated that the ^{13}C chemical shifts of the main chain amide carbonyl and $\text{C}\alpha$ carbons in polypeptides are conformation-dependent and thus the main chain conformation can be determined by the ^{13}C chemical shift position of the

main chain carbons.²⁵ Also, like polypeptides the conformation of long *n*-alkyl side chains can be determined by the ^{13}C chemical shift position.⁴⁶

In Figure 10 the ^{13}C CP/MAS NMR spectra of poly(γ -*n*-octadecyl L-glutamate) (POLG) with long *n*-alkyl $[-(\text{CH}_2)_{17}\text{CH}_3]$ side chains are shown over a wide range of temperatures from -40 to 230°C . Assignments for peaks are straightforward as indicated in the spectra. The ^{13}C chemical shift values of the amide carbonyl and $\text{C}\alpha$ carbons are 176.2 and 57.4 ppm, respectively. These values are characteristic of the right-handed α -helix conformation of the main chain of POLG. On the other hand, the assignment for peaks of *n*-alkyl side chains of POLG is performed by the using reference data on *n*-alkanes. At temperatures from -40 to 40°C , the ^{13}C chemical shift values of the inner CH_2 carbons of the side chains are 33 ppm. This means that the inner CH_2 carbons of the side chains take an all-*trans* zigzag conformation in the orthorhombic form. At temperatures above 50°C , the ^{13}C chemical shift value moves transitionally upfield by ca. 3 ppm. This means that *n*-alkyl side chains melt like liquid *n*-alkanes and then the fast exchange between the *trans* and *gauche* conformations occurs. Such an upfield shift occurs according to equation (1)

$$\delta_{\text{obs}} = \delta_o - 2\gamma f_g \quad (1)$$

where δ_{obs} and δ_o are the observed ^{13}C chemical shift and the ^{13}C chemical shift for the *trans* conformation, f_g is the fraction of the *gauche* conformation, and γ is attributed to the chemical shift difference (ca. 5.3 ppm) between the *trans* and *gauche* conformations.³⁰ At temperatures above 50°C , this polymer forms a thermotropic liquid crystalline state.

In Figure 10 it is shown that the broadening phenomenon for peaks of the main chain carbons can be explained on the basis of the consideration that when the orientation rate of the main chain in the liquid crystalline state is close to a frequency corresponding to the amplitude of the proton decoupling field (about 60 kHz for this experiment), the efficiency of the proton decoupling is considerably reduced and the line width becomes the maximum. Thus, it can be said that the main chain is undergoing reorientation at a frequency of ca. 60 kHz in the temperature range from 50 to 90°C .

In poly(L-glutamate) with long oleyl $[-(\text{CH}_2)_8\text{CH}=\text{CH}(\text{CH}_2)_7\text{CH}_3]$ side chains which contain a double bond (POLLG), the melting of the side chain crystallites is at a much lower temperature than that of POLG. This polymer forms thermotropic liquid crystals from lower temperature.⁴⁵ The spectral behavior is very similar to POLG.³⁴

2.3 Approach by Pulse Field-Gradient Spin-Echo ^1H NMR

2.3.1 Pulse Field-Gradient Spin-Echo ^1H NMR Measurements

In order to determine the diffusion coefficient of solvent and probe molecules in a gel, pulse field-gradient spin-echo (PFGSE) NMR is used. This method is very powerful.^{5,35,36} However, if one wants to determine relatively small diffusion coefficients with high accuracy, a strong strength of the field gradient must be used. We have designed two kinds of PFGSE NMR probe systems of generating the strength of the field

Figure 10 ^{13}C CP/MAS NMR spectra of poly(γ -octadecyl L-glutamate) over a wide range of temperatures

gradient pulse of 7.8 T m^{-1} and 22.8 T m^{-1} .³ This leads to a determination of the diffusion coefficient on the order of $10^{-14} \text{ m}^2 \text{ s}^{-1}$. As the PFGSE pulse sequence, two field gradient pulses are added to the ($\pi/2$ pulse $-\tau - \pi$ pulse) sequence, in which the first field gradient pulse is added at the mid position between the $\pi/2$ and π pulses (that is, at the position of τ^* after the $\pi/2$ pulse), and the second at the position of τ^* after the π pulse.³⁷

The relationship between the echo signal intensity and pulse field gradient parameters is given by equation (2)

$$A(\delta)/A(0) = \exp[-\gamma^2 G^2 D \delta^2 (D - \delta/3)] \quad (2)$$

where $A(\delta)$ and $A(0)$ are echo signal intensities at $t = 2\tau$ with and without the magnetic field gradient pulse, respectively, whose length is δ . τ is the pulse interval, γ the gyromagnetic ratio of the proton ($\gamma = 2.675 \times 10^8 \text{ rad T}^{-1} \text{ s}^{-1}$), G the field gradient strength, D the self-diffusion coefficient, and Δ the gradient pulse interval. The echo signal intensity was measured as a function of δ . The plot of $\ln[A(\delta)/A(0)]$ against $\gamma^2 G^2 \delta^2 (\Delta - \delta/3)$ gives a straight line with a slope of $-D$. Therefore, D can be determined from the slope. The τ , Δ and δ values employed in these experiments were 10, 10 and 0.001–0.12 ms, respectively. The D value of $2.5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ for water at 303 K was used as the calibration of the field gradient strength.³ The experimental error for the D value is estimated to be less than ca. 5%.

2.3.2 Diffusional Behavior of Synthetic Polymer Gels

2.3.2.1 Diffusional Behavior of Water in Poly(methacrylic acid) Gels

In order to investigate changes in the translational motion of water contained in the poly(methacrylic acid) (PMAA) gel by a change in the degree of crosslinking, the diffusion coefficient of water molecules ($D_{\text{H}_2\text{O}}$) in PMAA gels with the degree of swelling $Q = 3.4\text{--}105.8$ was determined by PFGSE ^1H NMR method at 300 K.³⁸ As seen from this table, $D_{\text{H}_2\text{O}}$ increases as Q is increased. This means that an increase in Q leads to an increase in mobility of water molecules. If the $D_{\text{H}_2\text{O}}$ increases are plotted against $Q^{1/3}$, it is seen from Figure 11 that $D_{\text{H}_2\text{O}}$ increases linearly from 1.37×10^{-9} to $2.19 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$ with increasing $Q^{1/3}$.³⁹ This shows that the translational molecular motion of water molecules in the PMAA gel increases with an increase in the degree of swelling. The $D_{\text{H}_2\text{O}}$ value of neat water at 300 K is $2.5 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. Therefore, it can be said that the translational molecular motion of water molecules in the gel is more restrained compared with that of neat water by the intermolecular interactions with the polymer network.

We are concerned with the reason why there exists a linear relationship between the $D_{\text{H}_2\text{O}}$ and $Q^{1/3}$. The volume for the gel that contains network polymer and water may be associated with $Q^{1/3}$. Assuming that the volume for the gel is a cube with the length of an edge being r , the degree of swelling for the

Figure 11 Plots of diffusion coefficient of water ($D_{\text{H}_2\text{O}}$) in PMAA gel against $Q^{1/3}$ at 300 K

gel is rearranged as equation (3)

$$Q = M_{\text{swollen}}/M_{\text{dry}} = (\rho_{\text{swollen}} \cdot V_{\text{swollen}})/M_{\text{dry}} = (\rho_{\text{swollen}}/M_{\text{dry}})r^3 \quad (3)$$

where ρ_{swollen} is the density of swollen polymer gel and V_{swollen} the volume of swollen polymer gel. M_{dry} is a constant. By rearranging equation (3), we obtain equation (4)

$$r = (M_{\text{dry}}/\rho_{\text{swollen}})^{1/3} Q^{1/3} \quad (4)$$

If Q is changed as a function of the degree of crosslinking of the gel, ρ_{swollen} does not change greatly (at 300 K $\rho_{\text{swollen}} = 1.001 \text{ g cm}^{-3}$ at $Q = 3.4$ and $\rho_{\text{swollen}} = 0.997 \times 10^3 \text{ Kg m}^{-3}$ at $Q = 106$). Therefore, it can be said that the length of an edge of the volume of the gel (r) is proportional to $Q^{1/3}$. This means that r of the volume containing a constant amount of network polymer increases with an increase in $Q^{1/3}$ and so the size of the polymer network in the gel expands the intermolecular distance between water molecules increases. For this, the molecular motion of molecules increases with an increase in $Q^{1/3}$. From the linear relationship between the $D_{\text{H}_2\text{O}}$ and $Q^{1/3}$, it can be said that the molecular motion of water depends on intermolecular distance.

2.3.2.2 Diffusional of Water and Poly(Ethylene Glycol) in Poly(Dimethylacrylamide) Gels

The diffusion coefficients of HDO (D_{HDO}) and poly(ethylene glycol) (PEG) contained in poly(dimethylacrylamide) (PDMAA) gel were determined by the PFGSE ^1H NMR method as described above at 303 K varying Q and molecular weight (M_w) of PEG.⁴⁰ The D_{HDO} values obtained were plotted against Q as shown in Figure 12. As seen from this figure, D_{HDO} increases as Q is increased, and is almost independent of M_w of PEG contained in the gel. The change of D_{HDO} in the small Q region is much larger than that in the large Q region. The D_{HDO} value in the large Q region asymptotically approaches that for HDO in neat D_2O ($2.22 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$). Therefore, it can be said that the intermolecular interaction between water and polymer network, of which the strength depends on the size of a network, restrains translational motion of the water. There is almost no effect on the molecular motion

Figure 12 Dependence of the diffusion coefficient of water molecules (D_{HDO}) on the degree of swelling (Q) in a PDMAA gel containing PEG with $M_w = 4250$ ($\square$), 10890 ($\blacktriangle$) and 20000 ($\circ$) at 303 K

of HDO by the change of M_w of PEG, indicating that the diffusion of HDO is independent of M_w of PEG.

We can understand these results by using the modified free volume theory proposed by Fujita.⁴¹ The diffusion coefficient is related to the friction ζ by the equation $D = kT/\zeta$, where k is the Boltzmann constant and T the absolute temperature. The dependence of ζ on solvent concentration is expressed as an exponential function of the fractional free volume f . Thus, we have equation (5)

$$D_{\text{HDO}} = D_{\text{HDO}}^0 \exp[Q^{-1}/(Q^{-1}f_{\text{solv}} - f_{\text{solv}}^2/\beta)] \quad (5)$$

The dynamic behavior of a probe polymer in a gel can be analyzed by the ratio of the screening length of polymer network to the dimensional size of PEG. It is shown that the diffusion of a particle in semi-dilute polymer solution and in a polymer gel is obeyed by the relation shown in equation (6)

$$D/D^0 = \exp(-\kappa R) \quad (6)$$

where D^0 is the diffusion coefficient of an isolated particle, R the radius of a particle and κ^{-1} the dynamical screening length of the polymer chain. When $D/D^0 = \kappa^{-1}$, κ^{-1} is equivalent to R . This relation has also been employed for elucidating the self-diffusion of random-coil polymers in solution and gel, in which the values of κ^{-1} are large enough for probe polymers to have the same motion as for a hard sphere. In these cases, the interchain hydrodynamic interactions more significantly contribute to the diffusion process compared with the topological constraints. For this, the hydrodynamic radius of a probe polymer can be replaced by R . When the topological constraints cannot be neglected compared with the interchain hydrodynamic interactions, D s becomes larger than the value expected from equation (6). When the diffusion coefficient of an isolated PEG (D_{PEG}^0) is determined from the diffusion coefficient of PEG in aqueous dilute solution ($D_{\text{PEG}}^{\text{soln}}$), it is necessary to take into account the change of local friction of polymer, which is estimated by the change for the

diffusion coefficient of the solvent. Then, D_{PEG}^0 is given by equation (7)

$$D_{\text{PEG}}^0 = D_{\text{PEG}}^{\text{soln}} / (D_{\text{HDO}}^{\text{neat}} / D_{\text{HDO}}) \quad (7)$$

where $D_{\text{HDO}}^{\text{neat}}$ is the diffusion coefficient of HDO in D_2O . In this work, the diffusion of water and PEG in a PDMAA gel has been analyzed by the above mentioned equations (6) and (7).

2.3.2.3 Diffusion Coefficient of HDO in a PDMAA Gel

We can more clearly understand the dynamic behavior of water in the gel system using equation (5) obtained from modified free volume theory.^{31,41} The solid curve obtained from a least-squares fitting to the experimental data using equation (5) is shown in Figure 12. The theoretical curve agrees well with the experimental data. From this result, the diffusion coefficient for HDO in infinite swollen gel ($Q \rightarrow \infty$) is obtained to be $D_{\text{PEG}}^0 = 2.16 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, which is lower than HDO in neat D_2O ($2.22 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$). This means that the diffusion coefficient for HDO in neat D_2O is different from the Q -extrapolated value to infinity given by the modified free volume theory for the diffusion concentration dependence. The diffusion coefficient for an isolated HDO molecule in bulk PDMAA ($Q \rightarrow 1$) obtained from Figure 12 was $2.5 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. It is seen that the translational motion of isolated water in bulk polymer is more strongly restrained compared to that in the gel. Further, it can be said that the rapid decrease of D_{HDO} in the small Q region can be explained by the decrease in free volume.

2.3.2.4 Diffusion Coefficient of PEG in a PDMAA Gel

In order to investigate the translational motion of PEG contained in PDMAA gel as a probe polymer, the diffusion coefficient of PEG (D_{PEG}) was determined by PGSE ^1H NMR at 303 K varying Q and M_w of PEG contained in the gel. It was found that D_{PEG} increases as Q is increased and also depends on M_w of PEG. The D_{PEG} value in the gel is smaller than that at 1% wt aqueous PEG solution ($D_{\text{PEG}}^{\text{soln}}$) at 303 K. Therefore, it can be said that the translational motion of PEG in the gel is more restrained by large intermolecular interaction with polymer network as compared with PEG in aqueous solution and that PEG with higher M_w is more strongly restrained.

Next, we are concerned with the relationship between the degree of restraint in molecular motion of PEG in the gel and the ratio of the screening length of polymer network to the size of PEG.⁴⁰ The dynamic behavior of PEG in the gel can be analyzed by using equation (6). The relationship between the dynamic screening length (κ^{-1}) and the concentration of network polymer (c) or the degree of swelling (Q) is expressed by equation (8)

$$\kappa^{-1} = c^u = Q^{-u} \quad (8)$$

where u may be a constant in the range from -0.5 to -1.0 , but depends largely on the polymer species. Substitution of equations (6) and (7) into equation (8) gives equation (9)

$$D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}} / D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}} = \exp(-Q^u R). \quad (9)$$

Figure 13 Plots of $\ln[(-\ln(D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}} / D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}})) D_{\text{PEG}}^{\text{soln}}]$ against $\ln Q$ at 303 K. M_w s of PEGs used are 4250 ($\square$), 10 890 ($\blacktriangle$) and 20 000 ($\circ$)

It is convenient to rewrite it in the form shown in equation (10)

$$\ln \left(-\ln \frac{D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}}}{D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}}} \right) = u \ln Q + \ln R. \quad (10)$$

In Figure 13, the $\ln[(-\ln(D_{\text{PEG}} D_{\text{HDO}}^{\text{neat}} / D_{\text{PEG}}^{\text{soln}} D_{\text{HDO}})) D_{\text{PEG}}^{\text{soln}}]$ value calculated using the experimental data is plotted against $\ln Q$. A straight line with a slope of -0.71 is obtained and so $u = -0.71$. Therefore, we have $\kappa^{-1} \sim Q^{0.71} = c^{-0.71}$. Depending on the nature of network and solvent, there are a variety of theoretical calculations for the concentration dependence of the dynamical screening length. de Gennes proposed that for flexible polymer chains in a gel with good solvent the relationship $\kappa^{-1} \sim c^{-0.71}$ is obtained.⁵⁴ This prediction is in agreement with the above experimental results.

2.3.2.5 Diffusion Behavior and Intermolecular Hydrogen-Bond Between Probe Polymer and Network Polymer in (N,N-Dimethylacrylamide–Acrylic Acid) Copolymer Gels

Molecular dynamics of a probe polymer is strongly affected in polymer gel systems with various kinds of intermolecular interactions between the probe polymer and the network polymer, such as hydrogen-bonding interactions, hydrophobic interactions, Coulomb interactions, etc. For example, by adding aqueous PEG solution to aqueous poly(acrylic acid) (PAA) solution the complex between PEG and PAA is formed by the formation of hydrogen bonds between the oxygen atoms of PEG and the carboxyl groups of PAA. Also, in PDMAA hydrogel the complex between PEG and PDMAA is formed by the same interaction. The justification for the formation of such complexes has been carried out by macroscopic methods such as viscosity measurements for solutions and mass measurements for gels. Nevertheless, in order to clarify more clearly such intermolecular interactions between probe polymer and network polymer in the gel systems, systematic studies by microscopic methods such as NMR spectroscopy are needed.⁴³

2.3.2.6 Diffusion Coefficient of HDO in (DMAA-AA) Copolymer Gels

The diffusion coefficients of HDO (D_{HDO}) contained in PDMAA gels, PAA gels and (DMAA-AA) copolymer gels with PEG were determined by PGSE ^1H NMR at 303 K varying Q and f_{AA} .⁴⁴ The D_{HDO} values obtained were plotted against Q . From this plot, it was found that the D_{HDO} increases as Q is increased. The molecular motion of HDO is not affected by a change of f_{AA} in the region of $f_{\text{AA}} < 0.9$. This means that the translational motion of the HDO molecule increases as the size of the network becomes larger. The dynamic behavior of solvent in a gel can be analyzed by the modified free volume theory. As described above D_{HDO} in a PDMAA gel can be expressed by equation (9). From a least-squares fit to the experimental data for PDMAA gels using equation (9), we can determine D_{HDO}^0 , f_{solv} and β to be $2.16 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$, 0.178 and 0.079, respectively. The calculation by using equation (6) and parameters obtained for PDMAA gels, agrees well with the experimental data obtained for (DMAA-AA) copolymer gels with f_{AA} value less than 0.9. This indicates that the diffusion of HDO is independent of the concentration of carboxylic acid group in this region. D_{HDO} s in PAA gels are larger than those in (DMAA-AA) copolymer gels. This may be because the concentration of H^+ ions dissociated from carboxylic acid groups in PAA gels, which diffuse faster than HDO, is higher than that in (DMAA-AA) copolymer gel.

2.3.2.7 Diffusion Coefficient of PEG in (DMAA-AA) Copolymer Gels

In order to investigate the translational motion of PEG contained in PDMAA gels and PAA gels as probe polymer, the diffusion coefficient of PEG (D_{PEG}) was determined by PGSE ^1H NMR at 303 K varying Q of the gel.⁴⁴ The D_{PEG} value in PDMAA gel is smaller than that in aqueous 1% wt PEG solution (dashed line), and increases as Q is increased. From the plot of $\ln(-\ln(D/D_0))$ against $\ln Q$, it was shown that this behavior is followed by $D/D_0 = \exp(-Q^2 R)$, and is similar to that mentioned above. Therefore, it can be said that the translational motion of PEG in PDMAA gel is restrained by hydrodynamic interaction with polymer network. This means that polymer network is working as only a spatial obstruction for the displacement of PEG. The D_{PEG} value in PAA gels is much smaller than that in PDMAA gel. This suggests that the loose complex of PEG and PAA network is formed by intermolecular hydrogen-bond interactions between the oxygen atoms of PEG and the carboxyl groups of PAA.⁴⁹ By addition of a small amount of HCl into the solution for the gel to be 0.15 mM in concentration, the gel shrinks and D_{PEG} is decreased. The complexation arises from intermolecular hydrogen-bond interaction between oxygen atoms of PEG and the carboxylic groups of AA units in the undissociated state as shown below. Therefore, it can be said that the addition of HCl leads to an increase in the amount of undissociated carboxylic groups and so enhances the formation of the complex and induces the shrinkage of the gel. This leads to slow diffusion of PEG. The addition of amine decreases the amount of dissociated carboxylic group and so inhibits the formation of the complex. This leads to fast diffusion of PEG and the swelling of the gel.

2.4 Diffusion Behavior of Polypeptide Gels

NMR methods involving pulsed magnetic field gradients provide one of the most attractive techniques for studies of molecular dynamics in polypeptide solution and gel systems. In particular, PFGSE NMR has been an invaluable tool in determining the anisotropic structures of polypeptide lyotropic liquid crystalline phase. Almost two decades ago, the first lateral diffusion coefficient of an amphiphile in a lamellar liquid crystalline phase was measured directly using PFGSE NMR. In recent years, the range of applications of NMR diffusion techniques has been growing rapidly, due to the great improvements in the NMR equipment for the diffusion microscopy. The diffusion behavior of solvent molecule in polypeptide gel system with α -helix-random coil transition, and on the diffusion behavior of solvent and probe n -alkanes molecules in polypeptide gel system with highly-oriented structures is introduced.

2.4.1 Diffusion Behavior of Solvents in Unoriented Polypeptide Gels

In high-resolution solid-state ^{13}C NMR experiments on cross-linked poly(γ -methyl L-glutamate) (PMLG) gel, we have found that the conformation of cross-linked PMLG with a mixture of chloroform (CHCl_3) and trifluoroacetic acid (TFA) largely depends on the solvent composition. The increase of volume fraction of TFA (f_{TFA}) in a mixture of CHCl_3 and TFA induces the α -helix-random coil transition of the main chain of cross-linked PMLG. CHCl_3 and TFA are sometimes so-called 'helix' and 'coil' solvents, respectively. It is important for gel science in polypeptide gel systems to elucidate how the translational motion of these solvents is affected when the main-chain of PMLG changes from the α -helix form to the random coil form. In such systems, the diffusion of solvent molecules contained in the polypeptide gel system strongly depends on the dynamics of polypeptide chains. As demonstrated above, PFGSE NMR gives useful information about the diffusion process of polymer gel system. From such a background, the dynamics of solvents in cross-linked PMLG gel with a mixture of CHCl_3 and TFA on going from the α -helix form to the random coil form through the diffusion coefficients were determined by PFGSE ^1H NMR.⁴⁵

2.4.2 Diffusion Behavior of Solvent and Probe-Molecules in Highly-Oriented Polypeptide Gels

As is well known, poly(γ -benzyl L-glutamate) (PBLG) forms the lyotropic liquid crystalline state in good solvents such as dichloromethane, dioxane, chloroform, etc. and when the PBLG liquid crystalline solution is placed in a strong magnetic field, the main chain can be oriented in the direction of the magnetic field. The molecular motion of solvent and PBLG in the liquid crystalline solution is considerably influenced by intermolecular interactions. By reacting highly-oriented PBLG chains with a cross-linker in a strong magnetic field, cross-linked PBLG gel with the highly-oriented α -helical chains is assumed to be formed.⁴⁶ We are interested in the problem of the diffusion process of solvent and n -alkanes with relatively extended conformation in the gel with anisotropic structure. The interest lies in the fact that n -alkanes are basic

molecules for understanding structure and dynamics of linear polymer chains.

According to the work on the orientation of *n*-alkanes in PBLG liquid crystalline solution by ^1H NMR, in which PBLG chains are highly oriented, *n*-alkanes being guest molecules are highly oriented to the magnetic field of an NMR magnet with the relatively extended conformation along the α -helical PBLG chains.⁴⁷ Also, as elucidated by NMR *n*-alkanes in the rotator phase take an extended conformation, which are rotating rapidly around the long axis. Thus, the diffusion coefficients for the directions parallel and perpendicular to the long axis differ.^{36,37}

With this as a background, cross-linked PBLG gels with highly-oriented α -helical chains are prepared. The diffusion coefficient of the solvent and *n*-alkanes in the gel for the directions parallel and perpendicular to the α -helical PBLG axis by using the PFGSE ^1H NMR method with strong field-gradient strength has been studied. In the liquid crystalline and gel states, the orientation of the PBLG chains can be determined by using high-resolution solid-state ^{13}C NMR.

2.4.3 Diffusional Process of Water in Starch Gels

The diffusional phenomena of compartmentalized water such as water in biological cells reflect the size and shape of the microstructure of the compartments and permeability of the barriers. The diffusion coefficients of water in corn starch gels, various wheat starch pastes and potato starch gels were measured.^{48–50} The diffusion coefficient (D_0) of water, the permeability of the barriers and the size of microstructure in potato starch gels have been determined by using the equation of restricted diffusional motion. The D_0 value is gradually decreased with an increase in the starch concentration and approaches a constant value of about $1.0 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$. If the diffusion comes from restricted diffusion by a structural barrier (a), the interbarrier diffusion coefficient may be equal to the diffusion coefficient of pure water. These results show that the diffusion coefficient is affected by obstruction and hydration effects by polymers that are dispersed in the water compartments. The compartmentalized water experiences higher viscosity and/or a longer lifetime in the hydration sphere of starch chains. The permeability is gradually decreased with an increase in the starch concentration and is reached a constant value at more than 30% concentration. This shows that the polymer network of barriers is more dense in the gels at higher concentration. This does not conflict with general experimental results that the higher is the starch concentration, the stiffer is corresponding gel. The value of the distance between the neighboring barriers is independent of the starch concentration for fresh gels. The increase in polymer concentration causes an increase in the density of barriers until the latter reaches its limiting value. The density of barriers reaches the limit value (at a concentration between 33.3 and 37.9%), further increase in the concentration causes a decrease in the a value. From these experimental results, the fresh starch gel structure may be pictured that some of the polymers aggregate to make the starch network of the gel and the remaining polymers, and/or parts of polymer chain, are free from the starch network and function as a solute in water compartmentalized by the network.

2.5 Diffusion in Poly(γ -*n*-octadecyl L-glutamate) and Poly(γ -oleyl L-glutamate) (POLLG) in the Thermotropic Liquid Crystalline State

In order to elucidate more deeply dynamics of the polypeptides in the thermotropic liquid crystalline state, it is important to have some knowledge of the magnitude of the diffusion coefficient and the anisotropy of the diffusion for the directions parallel and perpendicular to the α -helical chain axis. For measurements of the diffusion coefficients, it has been demonstrated that PFGSE ^1H NMR can provide useful information to elucidate the diffusion process of solvents for polypeptides in the liquid crystalline state, in addition to polymer gel systems and *n*-alkanes in the rotator phase like the liquid crystalline state.⁵¹

To this end, the isotropic and anisotropic diffusion coefficients of the POLG chain in an highly-oriented sample prepared in the magnetic field produced by 500 MHz NMR equipment and the isotropic diffusion coefficients of the POLLG chain in the thermotropic liquid crystalline state were measured over a wide range of temperatures.⁵² Further, T_2 of the side chain protons of POLG and POLLG were measured over a wide range of temperatures, and then the dynamics of the side chains were elucidated.

The highly-oriented POLG sample was prepared by the following procedure:

1. POLG was dissolved in 1,2-dichloroethane in an NMR glass tube to form the lyotropic liquid crystalline state.
2. the sample was placed in an NMR glass tube with a diameter of 5 mm and thence into the magnetic field of a 500 MHz NMR magnet for 60 hours until the POLG chains were aligned parallel to the magnetic field. The direction of the magnetic field was along the long axis of the NMR tube. After the full orientation of the polypeptide chains, solvent was vaporized from the NMR tube and then the highly-oriented film was obtained on the wall of the NMR tube. The complete orientation of the POLG chains in the film was confirmed by cross-polarized microscopy.

2.5.1 Diffusional Behavior and Dynamics of POLG and POLLG

In the spin-echo ^1H NMR spectra of POLG in the liquid crystalline state at 80 °C, an asymmetric relatively sharp signal appears, which has a chemical shift position (0.9 ppm) at the peak. This peak can be straightforwardly assigned to the methyl protons in the side chains. The upper shoulder peaks may be assigned to the methylene protons in the side chains. The peaks that come from the main chain protons such as α -CH proton and amide proton do not appear within the measurement temperature range. This is due to dipolar-broadened signal because of anisotropic molecular motion slow compared to the dipolar frequency, $\omega_0/2\gamma$. However, the spin-echo ^1H NMR spectra of POLLG are similar to those of POLG. Thus, the peak assignment can be made by comparison.

The plots of $\ln[A(\delta)/A(0)]$ against $\gamma^2 G^2 \delta^2 (\Delta - \delta/3)$ for the above-mentioned peak (at ca. 0.9 ppm) in the PFGSE ^1H NMR spectra of POLG and POLLG, become straight lines (not shown here). This shows that the diffusion of POLG and POLLG consists of a single component during the observation time. Hence, the diffusion coefficients for POLG and POLLG

Figure 14 Temperature dependence of the diffusion coefficients of POLG chains in the direction parallel and perpendicular to the α -helical axis magnetic field and the isotropic diffusion coefficients ($D_{\text{iso}} (= D_{\parallel} + 2D_{\perp})/3$), and the isotropic diffusion coefficients of POLLG within the temperature range from 30 to 80 °C

considered here were determined from the slope of the straight line as seen from equation (1).⁵²

The diffusion coefficients of the rod-like polypeptide chains for the directions parallel ($D_{\parallel}$) and perpendicular ($D_{\perp}$) to the α -helical chain axis were determined, and the isotropic diffusion coefficient (D_{iso}) was estimated by an average of the determined $D_{\parallel}$ and $D_{\perp}$ values as $(D_{\parallel} + 2D_{\perp})/3$ (Figure 14). As the temperature is increased from 60 to 80 °C, the $D_{\parallel}$ values of POLG in the liquid crystal state increase monotonically from 5.48×10^{-11} to $1.11 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ and, the $D_{\perp}$ values increase monotonically from 1.41×10^{-11} to $8.87 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$. The determined $D_{\parallel}$ and $D_{\perp}$ values at 60 °C are 5.48×10^{-11} and $1.41 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, respectively, and those at 80 °C are 1.11×10^{-10} and $8.87 \times 10^{-11} \text{ m}^2 \text{ s}^{-1}$, respectively. The diffusion of POLG in the thermotropic liquid crystalline state is anisotropic. The diffusion of the polypeptide along the long α -helical chain axis at 60 °C is roughly four times faster than that perpendicular to the long α -helical chain axis. At 80 °C, their diffusion coefficients are close to each other. As reported previously, the determined $D_{\parallel}$ and $D_{\perp}$ values of *n*-alkane, *n*-C₂₄H₅₀, in the rotator phase like the liquid crystalline state, which takes the all-*trans* zigzag conformation, are 1.64×10^{-10} and $2.70 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$, respectively. The diffusion of the *n*-alkane in the rotator phase along the long chain axis is slower by roughly two times than that perpendicular to the long chain axis. This is opposite to the results of POLG. From the number of amino acid residues of POLG (ca. 780) considered here, the α -helical chain length is roughly estimated to be ca. 117 nm by using the pitch of an α -helix chain per one amino acid residue to be 0.15 nm. However, the chain length of *n*-C₂₄H₅₀ with the all-*trans* zigzag conformation is roughly estimated to be ca. 1.8 nm. From these simple estimations, it is seen that the corresponding rod-like POLG is much longer than *n*-C₂₄H₅₀. This leads to the experimental finding that the diffusion of the POLG along the long α -helical chain axis is much faster than that perpendicular to the long α -helical chain axis.

As for POLLG, only the isotropic diffusion coefficients were determined for an interval of 10 °C in the temperature range from 30 to 80 °C (Figure 14). The diffusion coefficients of POLLG in the liquid crystalline state were determined as a function of temperature similarly to POLG. It is shown that with an increase in temperature from 30 to 80 °C, the D value increases gradually from 4.9×10^{-11} to $1.4 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. Let us compare these D_{iso} values with those of POLG calculated from the determined $D_{\parallel}$ and $D_{\perp}$ values. As the temperature is increased from 60 to 80 °C, the D_{iso} values of POLG increase gradually from 3.53×10^{-11} to $1.02 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$ and those of POLLG increase from 4.9×10^{-11} to $1.40 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$. At 60 °C, POLLG in the thermotropic liquid crystalline state diffuses faster by ca. 2.8 times than POLG irrespective of the same α -helical chain length and at 80 °C their diffusion rates are close to each other. At 60 °C such a large difference in D_{iso} between POLG and POLLG may come from large differences in their side-chain conformation and molecular motion (as seen from the T_2 experiments below). The melting temperature of side chain crystallites in POLG is ca. 60 °C and that of POLLG is below -40 °C as DSC measurements as reported previously.³⁴ This means that at 60 °C the side chains of POLLG are undergoing much faster *trans-gauche* exchange around the C-C bond compared with those of POLG, and the expansion of the side chains from the main chain in the former is much smaller than that of the latter. At a higher temperature (80 °C) their mobilities are close to each other. This leads to the difference in D_{iso} between POLG and POLLG.

In order to understand the diffusion process of the polypeptide in the thermotropic liquid crystalline state more thoroughly, the activation energy $E^{\ddagger}$ for diffusion process can be determined. $E^{\ddagger}$ can be obtained from the plots of $\ln D$ against $1/T$ within the temperature range from 60 to 80 °C. As for POLG, the measured values of $E^{\ddagger}$ are 33.4, 77.4 and 49.8 kJ mol⁻¹ for $D_{\parallel}$, $D_{\perp}$, and D_{iso} , respectively. However, the activation energy for D_{iso} of POLLG is determined to be 20.6 kJ mol⁻¹. From these experimental results, it can be said

that the activation energy for the diffusion process for POLLG in the thermotropic liquid crystalline state is much lower than that of POLG. In the case of POLG, the activation energy for the diffusion along the α -helical chain axis is much lower than that in the direction perpendicular to the α -helical chain axis.

1 INTRODUCTION

In incommensurate (I) systems¹ the periodicity q_I of at least one of the modulation waves cannot be expressed as a rational fraction of the periodicity q_L of the underlying lattice:

$$\frac{q_I}{q_L} \neq \frac{M}{N}, \quad M, N = 1, 2, 3, \dots \quad (1)$$

As a result, translational periodicity is lost in at least one dimension in spite of the existence of perfect long range order. In the general case, incommensurately modulated phases can be formed when several spatially periodic modulations with wave vectors q_i are incommensurate with the characteristic wave vectors of the underlying lattice. The modulation waves can be either of the plane wave (sinusoidal) type or soliton-like, consisting of nearly commensurate regions where the phase of the order parameter is practically constant and other regions (phase solitons) where it changes rapidly (Figure 1). Translational lattice periodicity is generally restored at lower temperatures by a ‘lock-in’ phase transition where the lattice modulation changes from incommensurate to commensurate.

The usefulness^{1,2} of NMR and NQR for the study of incommensurate systems is based on the fact that the resonance frequency varies in space in a way that reflects the spatial variation of the incommensurate modulation. In commensurate systems the number of magnetic resonance lines equals the (usually very small) number of physically nonequivalent nuclei per unit cell. In incommensurate systems, where the translational lattice periodicity is lost, there is in essence an infinite number of nonequivalent nuclei contributing to the magnetic resonance spectrum. Except in the narrow soliton limit, the incommensurate spectrum should be characterized by a quasicontinuous distribution of NMR frequencies instead of sharp lines as in commensurate crystals.

The nature of this distribution depends critically on the spatial variation of the phase of the incommensurate modulation, $\Phi = \Phi(x)$. A plane wave modulation thus produces a lineshape that differs strongly from the one expected for a multisoliton lattice. As the width of the

Figure 1 NMR lineshapes in I systems: (a) plane wave limit, (b) multisoliton lattice, (c) sequence of commensurate phases. (Reproduced by permission of Elsevier from R. Blinc²)

phase solitons decreases and the soliton–soliton spacing increases, more and more nuclei will find themselves in locally commensurate domains, so that new lines will appear at positions corresponding to the ones in the commensurate phase. These lines become stronger as the soliton density decreases, thereby allowing for a quantitative determination of the variation of the soliton density with temperature.

NMR and NQR are thus among the most sensitive means for studying the local nature of the incommensurate modulation.

2 SINGLE- q (1- q) MODULATED PLANE WAVE LIMIT

2.1 Lineshapes in the Plane Wave Limit

In the 1- q plane wave modulation limit the phase of the modulation wave is a linear function of the spatial coordinate x , and the incommensurate distortion is characterized by a single Fourier component q_I :

$$u = A \cos \Phi(x) = A \cos(q_I x + \Phi_0), \quad \Phi_0 = \text{const.} \quad (2)$$

In the local approximation the resonance frequency ν_i of a given nucleus depends only on the incommensurate displacement u_i of the resonating nucleus and the displacement of atoms moving in phase with it:

$$\nu_i = \nu[u_i(x_i)] \quad (3)$$

This relation can be expanded in powers of the displacements:

$$\nu_i = \nu_0 + a_1 u_i(x) + \frac{1}{2} a_2 u_i^2(x) + \dots \quad (4a)$$

yielding

$$\nu_i = \nu_0 + \nu_1 \cos \Phi(x) + \frac{1}{2} \nu_2 \cos^2 \Phi(x) + \dots \quad (4b)$$

2 INCOMMENSURATE SYSTEMS

where $\cos \Phi(x)$ nearly continuously takes on all values between +1 and -1, and where $\nu_1 \propto A \propto (T_I - T)^\beta$ and $\nu_2 \propto A^2 \propto (T_I - T)^{2\beta}$. Here the phase $\Phi(x)$ and the amplitude A of the modulation wave constitute the two-component order parameter of the 1- q normal-incommensurate phase transition.

The intensity of the resonance line in a frequency interval between ν and $\nu + d\nu$ is proportional to the number of nuclei resonating in this interval. Knowing the function $\nu_i = \nu[u_i(x)]$, one can calculate the frequency distribution $f(\nu)$ in I systems from

$$f(\nu) d\nu = C dx \quad (5)$$

or

$$f(\nu) = \frac{C}{\left| \frac{d\nu}{d\Phi} \frac{d\Phi}{dx} \right|} \quad (6)$$

In the plane wave limit $d\Phi/dx = \text{const}$ and $f(\nu)$ is determined simply by $d\nu/d\Phi$. In the multisoliton limit, however, $d\Phi/dx$ is a function of x (and thus of frequency) and thereby influences the lineshape. Typically, $d\nu/d\Phi$ is obtained from relationships like equation (4a).

2.1.1 The Linear and the Quadratic Cases

In the *linear case*, where $\nu(x) = \nu_0 + \nu_1 \cos \Phi(x)$, the frequency distribution is

$$f(\nu) = \frac{\text{const.}}{\sqrt{1 - (\nu - \nu_0)^2 \nu_1^2}} \quad (7a)$$

and is shown in Figure 1(a). Here the splitting $\Delta\nu$ between the two edge singularities at

$$\nu_{\pm} = \nu - \nu_0 = \pm \nu_1 \quad (7b)$$

increases with the critical exponent β , since

$$\Delta\nu = 2\nu_1 \propto (T_I - T)^\beta \quad (7c)$$

This lineshape has been observed¹ for the $^{87}\text{Rb } \frac{1}{2} \rightarrow -\frac{1}{2}$ transition in Rb_2ZnCl_4 (Figure 2).

In the *quadratic case*, where $\nu(x) = \nu_0 + \frac{1}{2}\nu_2 \cos^2 \Phi(x)$, the frequency distribution is

$$f(\nu) = \frac{\text{const.}}{\sqrt{(\nu - \nu_0) \left[\frac{1}{2}\nu_2 - (\nu - \nu_0) \right]}} \quad (8a)$$

The edge singularities occur now at

$$\nu_{(a)} = \nu_0 \quad (8b)$$

and

$$\nu_{(b)} = \nu_0 + \frac{\nu_2}{2} \quad (8c)$$

Figure 2 NMR lineshape of the $^{87}\text{Rb } \frac{1}{2} \rightarrow -\frac{1}{2}$ transition in the (i) paraelectric and (ii) incommensurate phases of Rb_2ZnCl_4 . (Reproduced by permission of the International Society of Magnetic Resonance from R. Blinc, *Bull. Magn. Reson.*, 1984, **6**, 38)

The position of the singularity at $\nu_{(a)}$ will not depend critically on temperature, but the position of the singularity $\nu_{(b)}$ will shift proportionally to the square of the order parameter so that

$$\Delta\nu = [\nu_{(b)} - \nu_{(a)}] \propto (T_I - T)^{2\beta} \quad (8d)$$

The quadratic case will be important for systems in which the linear term in equation (5) is forbidden by symmetry. If both linear and quadratic terms have to be taken into account, the frequency distribution will exhibit three singularities ν_+ , ν_- , and $\nu_{(c)}$ if $|\nu_2| \geq |\nu_1|$. These singularities will occur at

$$\nu_{\pm} = \nu_0 \pm \nu_1 + \frac{\nu_2}{2} \quad (9a)$$

and at

$$\nu_{(c)} = \nu_0 - \frac{\nu_1^2}{2\nu_2} \quad (9b)$$

2.1.2 Nonlocal Effects

In the general case the dependence of the resonance frequency on the lattice displacements is nonlocal² (i.e., the resonance frequency of the i th nucleus depends not only on its displacement but also on the displacement of other nuclei), as given by

$$\nu_i = \nu[u_i(x_i), u_j(x_j), \dots], \quad i \neq j \quad (10)$$

This dependence can reflect the nonlocal nature of such quantities as the electric field gradient (EFG) tensor or the chemical shift tensor, which, in addition to the external magnetic field, determine the NMR resonance frequency.

Only when the dominant contribution to the NMR resonance frequency comes from a region whose dimensions are small compared with the wavelength of the incommensurate modulation wave can the relationship between v_i and u_i be treated as local, so that equation (3) becomes strictly valid.²

In the nonlocal case equation (10) yields the spatial dependence of the NMR frequency²

$$\nu(x) = \nu_0 + \nu_1 \cos[\Phi(x) - \Phi_1] + \frac{1}{2}\{\nu_{2'} + \nu_{2''} \cos 2[\Phi(x) - \Phi_2]\} + \dots \quad (11a)$$

or, after introducing $\psi = \Phi - \Phi_2$ and $\tilde{\Phi} = \Phi_2 - \Phi_1$,

$$\nu(x) = \nu_0 + \nu_1 \cos[\psi(x) + \tilde{\Phi}] + \nu'_2 + \nu_2 \cos^2 \psi(x) + \dots \quad (11b)$$

where $\nu_2 = \nu_{2''}$ and $\nu'_2 = \frac{1}{2}(\nu_{2'} - \nu_2)$. Equation (11b) is similar to the local expression, equation (4b), except for the fact that there is now a phase shift $\tilde{\Phi} \neq 0$ between the linear and the quadratic terms and there is a uniform frequency shift $\nu'_2 \neq 0$.

In the *linear* approximation ($\nu_1 \neq 0$, $\nu_2 = \nu'_2 = 0$) there is no difference between the local and the nonlocal cases. In the *quadratic* approximation ($\nu_1 = 0$, $\nu_2 \neq 0$, $\nu'_2 \neq 0$) the frequency distribution is different from the one obtained in the local case. It is given by

$$f(\nu) = \frac{\text{const.}}{\sqrt{(\nu - \nu'_2 - \nu_0)(\nu_2 + \nu'_2 + \nu_0 - \nu)}} \quad (12a)$$

The edge singularities occur at

$$\nu - \nu_0 = \nu'_2 \quad (12b)$$

and

$$\nu - \nu_0 = \nu_2 + \nu'_2 \quad (12c)$$

The positions of both singularities now vary with temperature as $(T_1 - T)^{2\beta}$. The lineshapes and splittings for the local and nonlocal cases are illustrated in Figure 3 for both the linear and the quadratic approximations. If both linear and quadratic terms are present, the shape of the spectrum in the nonlocal case will depend strongly on the ratio between the magnitudes of ν_1 and ν'_2 and on the relative phase shift $\tilde{\Phi}$ between them. At lower temperatures, if $\tilde{\Phi}$ does not equal 0° or 90° , there will be *four* edge singularities and not *three*,² as in the local case.

2.1.3 Effects of Thermal Fluctuations

Let us now take into account thermal fluctuations³ of the phase,

$$\Phi(x, t) = \Phi(x) + \delta\Phi(x, t) \quad (13a)$$

and the amplitude,

$$A(x, t) = A_0 + \delta A(x, t) \quad (13b)$$

of the modulation wave. The NMR frequency of a given nucleus is now both time-dependent and space-dependent [i.e. $\Omega = \Omega(x, t)$]. Let us, for the sake of simplicity, assume that the NMR frequency $\Omega(x, t)$ of a nucleus at site x is related linearly to the nuclear displacement $u(x, t)$ at this site. Then³

$$\Omega(x, t) = \Omega_0 + au(x, t) \quad (14)$$

and

$$u(x, t) = A(x, t) \cos(q_1 x) + \delta\Phi(x, t) \sin(q_1 x) \quad (15)$$

The adiabatic NMR lineshape is given by

$$I(\omega) = \int G(t) \exp(i\omega t) dt \quad (16a)$$

where

$$G(t) = \exp(-i\Omega_0 t) \left\langle \left\langle \exp \left\{ -i \int_0^t [\Omega(x, t') - \Omega_0] dt' \right\} \right\rangle_x \right\rangle \quad (16b)$$

The inner brackets stand for an ensemble average and $\langle \rangle_x$ represents an average over the static inhomogeneous distribution of resonance frequencies discussed in the preceding section. Inserting equations (14) and (15) into equation (16b), we find the autocorrelation function $G(t)$ in the form

$$G(t) = \exp(-i\Omega_0 t) \langle \langle G_1(t) G_2(t) \rangle \rangle_x \quad (17)$$

Here $G_1(t)$ represents the static inhomogeneous frequency distribution limited by two edge singularities and $G_2(t)$ describes the effects of the amplitudon and phason thermal fluctuations of the modulation wave. Since the product of two functions in the time domain is equivalent to the convolution of their Fourier transforms in the frequency domain, the Fourier transform of $G(t)$ represents a convolution of the dynamic and static lineshapes.³ $I(\omega)$ is now given by

$$I(\omega) = \int_{-1}^{+1} \frac{dx}{\sqrt{1-x^2}} \int_0^\infty dt \exp[i(\omega - \Omega_0 - \Omega_1 x)t] \times \exp\{-[\omega_{\text{loc}1} t x^2 + (\omega_{\text{loc}2} t)^{3/2} (1-x^2)]\} \quad (18)$$

where $x = \cos(q_1 x)$, $\Omega_1 = aA_0$ and $\omega_{\text{loc}1}$ and $\omega_{\text{loc}2}$ are parameters³ that measure the relative sizes of amplitudon and phason fluctuations compared with the static order parameter. The fluctuation correction, determined by the Fourier transform of $G_2(t)$, determines the form of the incommensurate NMR spectrum close to the paraelectric-incommensurate transition T_1 . This feature is illustrated in Figure 4.

2.1.4 Sliding of the Modulation Wave

In NbSe₃ and other charge density wave (CDW) systems the CDW has been depinned⁴ by an applied electric field which was larger than a critical value. In such a case the NMR resonance frequencies are again both time- and space-dependent [$\Omega = \Omega(x, t)$]. The NMR lineshape is again given by equations (16a) and (16b). For the case of a *uniform sliding*

Figure 3 NMR lineshapes and T -dependence of splitting between edge singularities in the 'local' and 'nonlocal' cases: (a) linear, (b) quadratic, approximation. (Reproduced by permission of Elsevier from R. Blinc, P. Prelovšek, V. Rutar, J. Seliger, and S. Žumer, in 'Incommensurate Phases in Dielectrics', eds. R. Blinc and A. P. Levanyuk, 1986, Vols. I and II)

Figure 4 (a) Inhomogeneous and (b) homogeneous $^{87}\text{Rb } \frac{1}{2} \rightarrow -\frac{1}{2}$ lineshapes obtained by two-dimensional NMR in Rb_2ZnCl_4 close to T_1 . (Reproduced by permission of The American Physical Society from A. M. Fajdiga et al.³)

of the ‘plane wave’ like modulation wave with a velocity v and a wave vector q_1 we have

$$\begin{aligned} u(x, t) &= A \cos[q_1(x + vt) + \Phi_0] \\ &= A \cos(q_1x + \omega_v t + \Phi_0) \end{aligned} \quad (19a)$$

Uniform sliding of the modulation wave thus corresponds to a harmonic oscillation of a given nucleus with a frequency

$$\omega_v = q_1 v \quad (19b)$$

For

$$\begin{aligned} \Omega(x, t) &= \Omega_0 + au(x, t) \\ &= \Omega_0 + \Omega_1 \cos(q_1x + \omega_v t + \Phi_0) \end{aligned} \quad (20)$$

we get⁵

$$G(T) = J_0 \left[\frac{2}{w} \sin(\pi T) \right] \quad (21)$$

where J_0 is the cylindrical Bessel function of order zero, $T = (w/2\pi)\Omega_1 t$, and $w = \omega_v/\Omega_1$. In contrast to the case of a stochastic thermal motion, here $G(T)$ is periodic due to the uniform sliding of the modulation wave. This is an example of ‘coherent’ averaging, similar to the uniform magic angle spinning of a sample in the magnet.

The lineshape can be expressed⁵ as the Fourier transform of $G(T)$,

$$I(\omega) = \sum_{n=-\infty}^{+\infty} J_n^2 \left(\frac{1}{w} \right) \delta \left(\frac{\omega - \Omega_0}{\Omega_1} - nw \right) \quad (22)$$

It consists of a series of delta functions weighted by the square of the Bessel function of order n . In the general case a three-component lineshape is expected with peaks around $\omega = 0$ and $\omega = \pm \Omega_1$. The relative intensities of these lines and the positions of the center peaks vary strongly with w (Figure 5). For small sliding velocities the characteristic static incommensurate lineshape is preserved, but for large sliding velocities the incommensurate effects are motionally averaged out and a single sharp ‘paraelectric’ line at Ω_0 is obtained.

2.2 Lineshapes in the Multisoliton Lattice Limit

Consider, for the sake of simplicity, the static local case where the spatial variation of the NMR frequency $\nu(x)$ reflects the spatial variation of the frozen-out modulation wave $u(x)$. Here we have $\nu(x) = \nu[u(x)]$.

For a space-varying frequency $\nu(x)$ the spectral distribution at ν' is given by

$$f(\nu') = \int \delta[\nu' - \nu(x)] dx \quad (23a)$$

yielding

$$f(\nu) = \frac{\text{const.}}{\left| \frac{d\nu}{du} \right| \left| \frac{du}{d\Phi} \right| \left| \frac{d\Phi}{dx} \right|} \quad (23b)$$

Figure 5 Dependence of the incommensurate NMR lineshape $I(\omega)$ on the sliding velocity⁵ in the plane wave limit: (a) $w = 0.8$, (b) $w = 0.2$. The spectra have been convoluted with a Gaussian representing the width of the individual lines. (Reproduced by permission of Gordon and Breach Science Publishers from R. Blinc, *Phase Transitions*, 1988, **11**, 255)

The lineshape will be peaked whenever

$$(i) \quad d\nu/du \rightarrow 0 \quad (23c)$$

$$(ii) \quad du/d\Phi \rightarrow 0 \quad (23d)$$

or

$$(iii) \quad d\Phi/dx \rightarrow 0 \quad (23e)$$

Whereas points (i) and (ii) give rise to singularities in the spectrum in the plane wave limit, it is point (iii), $d\Phi/dx \rightarrow 0$, that is unique to the multisoliton lattice limit, and which allows for a determination of the soliton density. Here the spatial variation of the phase $\Phi(x)$ of the modulation wave is determined from the nonlinear sine–Gordon equation

$$\frac{d^2 \Phi}{dx^2} = -\frac{n \gamma}{2 \kappa} A_0^{n-2} \sin(n\Phi) \quad (24)$$

Here n represents the lowest power of the ‘lock-in’ term^{1,2,6} describing the effect of the discrete crystal lattice; γ is a

Figure 6 Spatial variation of the phase of the modulation wave for different soliton densities $n_s = d_0/x_0$. Here d_0 is the soliton width and x_0 the intersoliton spacing. (Reproduced by permission of Elsevier from R. Blinc, P. Prelovšek, V. Rutar, J. Seliger, and S. Žumer, in 'Incommensurate Phases in Dielectrics', eds. R. Blinc and A. P. Levanyuk, 1986, Vols. I and II)

coefficient describing the strength of the lock-in term, and κ is an elastic constant.

It should be noted that $n = 10$ for $[\text{N}(\text{CH}_3)_4]_2\text{ZnCl}_4$, $n = 6$ for Rb_2ZnCl_4 , $n = 4$ for $(\text{NH}_4)_2\text{BeF}_4$, and $n = 2$ for chiral smectic liquid crystals in an external magnetic field.²

Close to T_I , where $A_0 \propto (T_I - T)^\beta \rightarrow 0$, $\Phi(x)$ is nearly linear in x and we are in the 'plane wave' modulation limit. At lower temperatures, where A_0 is larger, Φ becomes nonlinear in x and the multisoliton lattice limit is approached. Nearly commensurate regions where $\Phi(x) \approx \text{const.}$ are separated by soliton-like 'discommensurations' where the phase changes rapidly (Figure 6). The soliton density¹

$$n_s = \frac{d_0}{x_0} \quad (25)$$

is the ratio of the soliton width d_0 to the intersoliton spacing x_0 and corresponds to the volume fraction of the crystal occupied by the phase soliton domain walls (i.e. the 'discommensurations'). The soliton density is unity in the plane wave limit just below T_I and zero at the 'lock-in' transition to the commensurate phase at T , where $x_0 \rightarrow \infty$.

By a straightforward integration of equation (24) we can obtain $d\Phi/dx$ so that $f(v)$ becomes:

$$f(v) = \frac{\text{const.}}{\left| \frac{dv}{du} \right| \left| \frac{du}{d\Phi} \right| \sqrt{\Delta^2 + \cos^2 \left\{ \frac{1}{2} n [\Phi(x) - \Phi_0] \right\}}} \quad (26a)$$

where Φ_0 is an initial phase that depends on the position of the nucleus in the paraelectric unit cell. The integration constant Δ^2 is related to the soliton density n_s via²

$$n_s = \frac{\pi/2}{K(k)} \quad (26b)$$

where

$$k = \frac{1}{\sqrt{1 + \Delta^2}} \quad (26c)$$

and $K(k)$ is the complete elliptic integral of the first kind

$$K(k) = \int_0^{\pi/2} \frac{d\Phi}{\sqrt{1 - k^2 \sin^2 \Phi}} \quad (26d)$$

Δ^2 is obtained experimentally by fitting the observed lineshape to equation (26a).

It should be noted² that for $T \rightarrow T_I$, $A_0 \rightarrow 0$, $k^2 \rightarrow 0$, $\Delta^2 \rightarrow \infty$, and $K(k) \rightarrow \pi/2$ so that $n_s \rightarrow 1$. For $T \rightarrow T_c$, however, $k^2 \rightarrow 1$, $K(k) \rightarrow \infty$, and $n_s \rightarrow 0$.

Equation (26a) yields the same lineshape as that obtained in the plane wave limit if $\Delta^2 \gg 1$, but up to n new lines are found² in the multisoliton limit (where $\Delta^2 \ll 1$). The new lines are in addition to the singularities formed in the plane wave limit and appear for $\Delta^2 \ll 1$ when $\cos^2 \left\{ \frac{1}{2} n [\Phi(x) - \Phi_0] \right\} = 0$, i.e. when

$$\Phi = (2m + 1)\pi/n + \Phi_0, \quad m = 0, 1, 2, \dots, n - 1 \quad (27)$$

At special values of Φ_0 the number of new 'commensurate' lines will be smaller than n . The gradual appearance of these lines⁷ is illustrated in Figure 7 and the corresponding temperature dependence of n_s is shown in Figure 8.

2.3 Long Period Commensurate Phases

In incommensurate phases the periodicity q_I of the order parameter and the periodicity of the basic lattice cannot be

Figure 7 $^{87}\text{Rb } \frac{1}{2} \rightarrow -\frac{1}{2}$ NMR lineshapes for different soliton densities n_s . (Reproduced by permission of the International Society of Magnetic Resonance from R. Blinc, *Bull. Magn. Reson.*, 1984, **6**, 38)

Figure 8 T -dependence of soliton density n_s in Rb_2ZnCl_4 . (Reproduced by permission of the International Society of Magnetic Resonance from R. Blinc, *Bull. Magn. Reson.*, 1984, **6**, 38)

expressed as a ratio of two integers, resulting in a loss of translational periodicity. Long period commensurate (C) phases exist² where $\mathbf{q}_1$ varies in steps and ‘locks in’ at an infinity of rational multiples of the periodicity of the basic lattice. The T – $\mathbf{q}_1$ phase diagram of such a system consists of an infinity of C phases which may or may not be separated by I phases in which $\mathbf{q}_1$ varies continuously with T . The first of these two cases is known as the incomplete and the second as the complete devil’s staircase.^{6,8} Such phases have been observed in betaine calcium chloride dihydrate,^{9,10} thiourea, $[\text{N}(\text{CH}_3)_4]_2\text{ZnCl}_4$ and other systems.

In the C region the phase becomes a constant, $\Phi(x) = K$, which is equivalent to a renormalization of the initial phase, $\Phi_0 \rightarrow \tilde{\Phi}_0$. If the commensurate wave vector $\mathbf{q}_c^x$ in the presence of a devil’s staircase is expressed as

$$\mathbf{q}_c^x = \mathbf{b}^x \frac{M}{N} \quad (28a)$$

where $\mathbf{b}^x$ is a reciprocal lattice vector of the high-temperature phase and M and N are integers, the NMR frequency can be expressed¹⁰ in the linear case as

$$\nu^{(M,N)} = \nu_0 + \nu_1 \cos\left(2\pi \frac{M}{N} + \tilde{\Phi}_0\right), \quad M = 0, 1, \dots, N-1 \quad (28b)$$

Equation (28b) yields the NMR frequencies in a commensurate unit cell which is N times larger than the high-temperature unit cell. The frequency distribution $f(\nu)$ is now obtained¹⁰ as

$$f(\nu) = \frac{1}{N} \sum_{M=0}^{N-1} \delta\left[\nu - \nu_0 - \nu_1 \cos\left(2\pi \frac{M}{N} + \tilde{\Phi}_0\right)\right] \quad (28c)$$

which yields N commensurate lines with a splitting $\Delta\nu \approx 2\nu_1/N - 1$. For $N \rightarrow \infty$ the incommensurate lineshape is recovered. However, because of the natural width of the individual NMR lines, it is hard to discriminate between I phases and long period C phases for $N > 20$.

2.4 T_1 Effects

Spin–lattice relaxation is often due to phonon scattering processes which are accompanied by spin flips. The probability of such processes increases with increasing phonon occupation number and increasing relative displacement of the lattice nuclei leading to fluctuations in the EFG, the chemical shift, or the magnetic dipolar coupling tensors. In translationally periodic crystals undergoing structural phase transitions, the main contribution to spin–lattice relaxation is usually made by the lowest frequency soft optic modes. The contribution of long wavelength acoustic modes is usually negligible, since the relative displacements of the nearest neighbors are too small.

The situation is quite different in I systems. The excitation spectrum consists here in the simplest case of two modes: an optic-like amplitudon branch, $A = A_0 + \delta A(t)$, corresponding to oscillations of the amplitude of the modulation wave, and an acoustic-like phason branch, $\Phi = \Phi_0 + \delta\Phi(t)$, representing the sliding of the I modulation wave. The phason with wave vector $\mathbf{q}_1$ corresponds to the Goldstone mode, which recovers the broken translational periodicity of the I phase. It is gapless in the continuum limit, since the free energy of the I phase does not depend on the phase of the modulation wave. In contrast to acoustic phonons, the phason has zero frequency at a nonzero wave vector $\mathbf{q}_1$. The number of thermally excited phasons is of the order of the number of acoustic phonons, but the relative nuclear displacements are not small since $\mathbf{q}_1 \neq 0$. This leads to an extremely efficient spin–lattice relaxation mechanism for quadrupolar nuclei. The rather short value of the phason-induced T_1 is thus one of the prominent signs of the presence of an I phase.

2.4.1 Amplitudons and Phasons: One Phonon Processes

In the presence of pinning effects the phason dispersion relation is

$$\omega_\Phi^2 = \Delta_\Phi^2 + \kappa(q - q_1)^2, \quad T < T_1 \quad (29a)$$

where Δ_Φ is the phason gap which vanishes in the absence of pinning in the continuum limit. The amplitudon dispersion relation, however, is

$$\omega_A^2 = \Delta_A^2 + \kappa(q - q_1)^2, \quad T < T_1 \quad (29b)$$

where

$$\Delta_A^2 = 2a(T_1 - T), \quad T < T_1 \quad (29c)$$

One-phonon processes will dominate the relaxation rate if the above order parameter fluctuation modes are overdamped. In the simplest ‘linear’ case we find within the ‘local’ model that T_1^{-1} varies over the I frequency distribution $f(\nu)$ as

$$\frac{1}{T_1} = \frac{1}{T_{1A}} X^2 + \frac{1}{T_{1\Phi}} (1 - X^2) \quad (30a)$$

where

$$X = \frac{\nu - \nu_0}{\nu_1} \quad (30b)$$

and T_{1A} and $T_{1\Phi}$ are the spin–lattice relaxation times for amplitudons and phasons, respectively. The two ‘edge’ singularities, where $X = \pm 1$, will thus be relaxed by amplitudons whereas the central part of $f(\nu)$, where $X = 0$, will be relaxed by phasons.¹¹ Here one finds¹¹

$$T_{1\Phi}^{-1} = C \frac{\pi}{2\sqrt{2}} \kappa^{-3/2} \sqrt{\frac{\Gamma_\Phi}{\Omega_0}} \quad (31a)$$

if

$$\Gamma_\Phi \gg \Omega_0 \gg \Delta_\Phi \quad (31b)$$

i.e. if the phason gap is smaller than the Larmor frequency Ω_0 . Γ_Φ is the phason damping constant ($\Gamma_\Phi \approx 10^{11} - 10^{12}$ Hz) and C is a constant proportional both to the square of the fluctuating quadrupole coupling tensor components and to kT .

If, however, the phason gap Δ_Φ is larger than the Larmor frequency Ω_0 , $T_{1\Phi}$ depends on the phason gap Δ_Φ :

$$T_{1\Phi}^{-1} = C \frac{\pi}{4} \kappa^{-3/2} \frac{\Gamma_\Phi}{\Delta_\Phi} \quad (32a)$$

if

$$\Delta_\Phi \gg \Omega_0 \quad (32b)$$

The amplitudon-induced spin–lattice relaxation rate is similarly obtained as

$$T_{1A}^{-1} = C \frac{\pi}{4} \kappa^{-3/2} \frac{\Gamma_A}{\Delta_A} \quad (33a)$$

Since $\Gamma_A \approx \Gamma_\Phi = \Gamma$ and $\Omega_0 \ll \Gamma \ll \Delta_A$, one gets

$$\frac{T_{1\Phi}}{T_{1A}} = \frac{\Delta_\Phi}{\Delta_A}, \quad \Delta_\Phi \gg \Omega_0 \quad (33b)$$

and

$$\frac{T_{1\Phi}}{T_{1A}} = \frac{\sqrt{\Omega_0 \Gamma}}{\Delta_A}, \quad \Delta_\Phi \leq \Omega_0 \quad (33c)$$

A measurement of $T_{1\Phi}$ and T_{1A} in the I phase thus permits a determination of Δ_Φ in terms of Δ_A , which can be easily determined by Raman or neutron scattering.² Such a measurement is performed by selective frequency irradiation of the various parts of $f(\nu)$ and a determination of the variation of the effective T_1^{-1} over the incommensurate lineshape (Figure 9).

The above theoretical predictions have been verified by numerous experiments^{1,2} (Figure 10). It should be noted that only in biphenyl¹² and in bis(4-chlorophenyl) sulfone¹³ was the phason gap found to be smaller than Ω_0 . In all other I systems investigated so far $\Delta_\Phi > \Omega_0$, since the modulation wave is pinned by defects or discrete lattice effects.

2.4.2 Amplitudons and Phasons: Raman Processes

For two-phonon Raman processes the spin–lattice relaxation rates are proportional¹¹ to $(kT)^2$, in contrast to the direct

Figure 9 Variation of the effective ^{14}N spin–lattice relaxation rate over the incommensurate ^{14}N NMR lineshape in $[N(CH_3)_4]_2 ZnCl_4$. (Reproduced by permission of Elsevier from R. Blinc, P. Prelovšek, V. Rutar, J. Seliger, and S. Žumer, in ‘Incommensurate Phases in Dielectrics’, eds. R. Blinc and A. P. Levanyuk, 1986, Vols. I and II)

Figure 10 Temperature dependence of the $^{87}Rb \frac{1}{2} \rightarrow -\frac{1}{2}$ spin–lattice relaxation time in the P, I, and C phases of Rb_2ZnCl_4 . (Reproduced by permission of Elsevier from R. Blinc, P. Prelovšek, V. Rutar, J. Seliger, and S. Žumer, in ‘Incommensurate Phases in Dielectrics’, eds. R. Blinc and A. P. Levanyuk, 1986, Vols. I and II)

case where they are proportional to kT . The frequency variation of T_1 over the inhomogeneous frequency distribution is here slightly more complicated. For the ‘linear’ case one finds¹⁴ that

$$\frac{1}{T_1} = \frac{1}{T_{1AA}} X^4 + \frac{1}{T_{1\Phi\Phi}} (1 - X^2)^2 + \left(\frac{1}{T_{1A\Phi}} + \frac{1}{T_{1\Phi A}} \right) X^2 (1 - X^2) \quad (34)$$

where T_{1AA}^{-1} and $T_{1\Phi\Phi}^{-1}$ are spin–lattice relaxation rates for processes involving two amplitudons and two phasons, respectively, and $T_{1A\Phi}^{-1} = T_{1\Phi A}^{-1}$ are for Raman processes involving one amplitudon and one phason. By selective irradiation we can measure T_{1AA} at $X = 1$ and $T_{1\Phi\Phi}$ at $X = 0$. Using this technique the phason gap in TlBr_4 has been determined.¹⁴ Furthermore, the $(kT)^2$ dependence predicted for Raman relaxation was confirmed experimentally¹⁴ in this system.

2.4.3 T_1 in the Multisoliton Lattice Limit

The periodicity of the multisoliton lattice results in a splitting of the phason mode^{1,2,6} [equation (29a)] into two branches separated by an energy gap: an ‘acoustic-like’ branch for $|k_z| < \pi/x_0$ and an ‘optic-like’ branch for $|k_z| > \pi/x_0$ (Figure 11). The ‘acoustic’ branch corresponds to phase oscillations of the multisoliton lattice, whereas the ‘optic-like’ branch corresponds to phase oscillations in the commensurate regions. On approaching the ‘lock-in’ transition the ‘acoustic-like’ branch vanishes (Figure 11) resulting in a critical decrease¹³ of the ‘acoustic phason’-induced spin–lattice relaxation rate

$$\left(\frac{1}{T_1} \right)_{\text{ac}, \Phi} = C[(\pi \Gamma_{\Phi} \Lambda_{\perp}^2)/(2\Delta_{\Phi}^4)] x_0^{-1} \quad (35a)$$

where

$$x_0 = \ln(1 - T_c/T) \quad (35b)$$

and $\Lambda_{\perp}$ is the maximum value of the corresponding wave vector components. This effect has indeed been observed¹³ in Rb_2ZnCl_4 close to the ‘lock-in’ transition T_c (Figure 12).

3 MULTIPLE- q MODULATED INCOMMENSURATE SYSTEMS

Consider now the NMR properties of I systems with a $2n$ -component order parameter,

$$Q_{i\pm} = A_i \exp(\pm i\Phi_i), \quad i = 1, 2, \dots, n \quad (36a)$$

corresponding to an n -dimensional modulation wave

$$u = \sum_{p=1}^n A_p \cos[\Phi_p(\mathbf{r}) + \Phi_{p0}] \quad (36b)$$

Figure 11 Temperature dependence of the phason dispersion relation in a multisoliton lattice showing the splitting into ‘acoustic-like’ and ‘optic-like’ branches. The acoustic-like branch vanishes on approaching the lock-in transition T_c . (Reproduced by permission of The American Physical Society from R. Blinc et al.¹³)

Figure 12 (a) Temperature dependence of the ‘acoustic-like’ phason-induced ^{87}Rb spin–lattice relaxation rate $T - 1/T_1$, and (b) temperature dependence of the soliton density n_s in Rb_2ZnCl_4 as $T \rightarrow T_c$. (Reproduced by permission of The American Physical Society from R. Blinc et al.¹³)

For the sake of simplicity let us first assume that the relation between the NMR frequency and the incommensurate displacements is purely local and linear, so that

$$\nu(\Phi_1, \dots, \Phi_n) = \nu_0 + \sum_{i=1}^n \nu_i \cos \Phi_i \quad (37a)$$

Here ν_i is proportional to the amplitude A_i of the i th component of the modulation wave. In the plane wave limit

we have

$$\Phi_i = \mathbf{q}_i \cdot \mathbf{r}_i + \Phi_{pi0} \quad (37b)$$

where the modulation vectors $\mathbf{q}_i$ are incommensurate to the basic crystal lattice. The phases Φ_i take on any value in the interval $(-\infty, +\infty)$ with equal probability. The frequency distribution is now obtained¹⁵ as

$$f(\nu) = \int \cdots \int d\Phi_1 d\Phi_2 \cdots d\Phi_n \delta[\nu - \nu(\Phi_1, \dots, \Phi_n)] \quad (38a)$$

When the modulation waves are independent, $f(\nu)$ is given by a multiple convolution,

$$f(\nu) = \int_{-\infty}^{+\infty} f_1(\nu'_1) f_2(\nu'_2) \cdots f_{n-1}(\nu'_{n-1}) \times f_n\left(\nu - \sum_{j=1}^{n-1} \nu'_j\right) d\nu'_1 d\nu'_2 \cdots d\nu'_{n-1} \quad (38b)$$

of frequency distributions $f_i(\nu)$ for purely one-dimensional modulations.¹⁶

The modulation waves are independent if the number of modulation waves is smaller than the dimension of space spanned by the corresponding wave vectors and if the initial phases Φ_{i0} are not correlated.¹⁵ In quartz,² for instance, the three modulation waves are coplanar ($|\mathbf{q}_1| = |\mathbf{q}_2| = |\mathbf{q}_3|$ and $\mathbf{q}_1 + \mathbf{q}_2 + \mathbf{q}_3 = 0$) and therefore correlated so that the 3- $\mathbf{q}$ case is in fact reduced to a 2- $\mathbf{q}$ case.

The NMR lineshapes $f(\nu)$ for multiple- $\mathbf{q}$ modulations are illustrated in Figure 13 for the linear case in both the plane wave and the multisoliton lattice limits ($n_s = 0.6$).

3.1 Lineshapes in 2- $\mathbf{q}$ Modulated Systems

Let us now consider a case where the angle between the two modulation vectors $\mathbf{q}_1$ and $\mathbf{q}_2$ equals $\gamma \neq 0$. Here

$$u = A_1 \cos \Phi_1 + A_2 \cos \Phi_2 \quad (39a)$$

where $\Phi_1 = \mathbf{q}_1 x$ and $\Phi_2 = \mathbf{q}_2 x \cos \gamma + \mathbf{q}_2 y \sin \gamma + \Phi_0$. The lineshape $f(\nu)$ is given by

$$f(\nu) = \int_{-\infty}^{+\infty} f_1(\nu') f_2(\nu - \nu') d\nu' \quad (39b)$$

For $A_1 = A_2$ and $\nu_1 = \nu_2$ the lineshape reduces to a central logarithmic singularity

$$f(\nu) = -\ln[(\nu - \nu_0)/\nu_1]/\nu_1 \quad (39c)$$

for $\nu - \nu_0 \rightarrow 0$ (Figure 13). $f(\nu)$ does not depend on γ or on the ratio $|\mathbf{q}_1|/|\mathbf{q}_2|$ since the two modulation waves are independent. If $\gamma = 0$, so that $\mathbf{q}_1$ is parallel to $\mathbf{q}_2$, this is still true as long as $|\mathbf{q}_1|$ is incommensurate to $|\mathbf{q}_2|$. If however the ratio $|\mathbf{q}_1|/|\mathbf{q}_2|$ is commensurate, the two waves are correlated and the lineshape is the same as in the 1- $\mathbf{q}$ case. Barium sodium niobate, biphenyl, and BaMnF₄ represent examples of 2- $\mathbf{q}$ modulated systems.²

Blinc, P. Prelovšek, V. Rutar, J. Seliger, and S. Žumer, in 'Incommensurate Phases in Dielectrics', eds. R. Blinc and A. P. Levanyuk, 1986, Vols. I and II)

Figure 14 Comparison between the experimental and theoretical ^{75}As NQR lineshapes in the 3- q modulated I phase of proustite

Figure 15 Relation between $T - 1/T_1$ and frequency shift $\nu - \nu_0$ for (a) 1- q , (b) 2- q , and (c) 3- q , I modulation. The shaded area designates the distribution of $T - 1/T_1$ values. (Reproduced by permission of The American Physical Society from R. Blinc and S. Žumer¹⁵)

3.2 Lineshapes in 3- q Modulated Systems

For three independent I modulation waves, $f(\nu)$ is given by a double convolution

$$f(\nu) = \int_{-\infty}^{+\infty} \int_{-\infty}^{+\infty} f_1(\nu'_1) f_2(\nu'_2) f_3(\nu - (\nu'_1 + \nu'_2)) d\nu'_1 d\nu'_2 \quad (39d)$$

The frequency distribution function (Figure 13) has no singularities, but the derivatives have singular points. In the general case where not only linear but also higher order terms contribute as well, a bell-shaped curve is expected for $f(\nu)$.

Such a bell-shaped curve has indeed been observed^{17,18} in the ^{75}As NQR of proustite, Ag_3AsS_3 . It can be described¹⁸ (Figure 14) by

$$\begin{aligned} \nu = & \nu_0 + \nu_1[\cos(\mathbf{q}_1 \cdot \mathbf{r}) + \cos(\mathbf{q}_2 \cdot \mathbf{r}) + \cos(\mathbf{q}_3 \cdot \mathbf{r})] \\ & + \nu_{21}[\cos(2\mathbf{q}_1 \cdot \mathbf{r} + \beta) + \cos(2\mathbf{q}_2 \cdot \mathbf{r} + \beta) + \cos(2\mathbf{q}_3 \cdot \mathbf{r} + \beta)] \\ & + \nu_{22}\{\cos[(\mathbf{q}_1 - \mathbf{q}_2) \cdot \mathbf{r}] + \cos[(\mathbf{q}_2 - \mathbf{q}_3) \cdot \mathbf{r}] \\ & + \cos[(\mathbf{q}_3 - \mathbf{q}_1) \cdot \mathbf{r}]\} + \nu_{23}\{\cos[(\mathbf{q}_1 + \mathbf{q}_2) \cdot \mathbf{r} + \gamma] \\ & + \cos[(\mathbf{q}_2 + \mathbf{q}_3) \cdot \mathbf{r} + \gamma] + \cos[(\mathbf{q}_3 + \mathbf{q}_1) \cdot \mathbf{r} + \gamma]\} \end{aligned} \quad (40)$$

3.3 T_1 Effects in Multiple- q Modulated Incommensurate Systems

For a system with n modulation waves linearly and locally related to the NMR frequency [equation (32a)] the spin-lattice relaxation rate for one-phonon processes can be expressed as

$$\frac{1}{T_1}(\Phi_1, \Phi_2, \dots, \Phi_n) = K \sum_{i=1}^n (\cos^2 \Phi_i J_{A,i} + \sin^2 \Phi_i J_{\Phi,i}) \quad (41)$$

where $J_{A,i}$ and $J_{\Phi,i}$ are local spectral densities of the amplitudon and phason order parameter fluctuation modes. Even though there is a simple relation between the effective spin-lattice relaxation rate $1/T_1$ and the NMR frequency in

Figure 16 Distributions of relaxation rates $F(T_1^{-1})$ for (a) 2- q , and (b) 3- q , I modulations. (Reproduced by permission of The American Physical Society from R. Blinc and S. Žumer¹⁵)

1- q modulated systems,^{1,2} this is not the case in multiple- q systems. At any given frequency there is now a distribution of spin-lattice relaxation rates:¹⁵

$$F(T_1^{-1}, \nu) = \int \cdots \int d\Phi_1 d\Phi_2 \cdots d\Phi_n \delta[\nu - \nu(\Phi_1, \Phi_2, \dots, \Phi_n)] \times \delta[T_1^{-1} - T_1'^{-1}(\Phi_1, \Phi_2, \dots, \Phi_n)] \quad (42)$$

The relationship between T_1^{-1} and the frequency shift $\nu - \nu_0$ for multiple- q modulations are illustrated in Figure 15, and the corresponding relaxation rate distributions $F(T_1^{-1})$ are shown¹⁵ in Figure 16.

1 INTRODUCTION

Two recent important developments of metallic alloys are the discoveries of quasicrystalline (QC) alloys and bulk metallic glasses (BMGs). In both cases, NMR studies have obtained crucial information that is important for the understanding of the novel properties of these systems. Discovered in 1984, QC alloys possess long-range translational and orientational orders, which lead to sharp Bragg diffraction peaks.¹ However, the diffraction patterns display point-group symmetry, such as icosahedral (i) symmetry, incompatible with periodicity.¹ Thus, QC alloys belong to a new class of solids unlike crystalline and glassy materials. In addition to their fascinating structure, QC alloys also possess novel physical properties such as the extremely low electric conductivity.² In this article we will focus on how NMR provides crucial information on the electronic structures of these QC alloys. Unlike crystalline and QC solids, glasses lack both long-range translational and orientational orders. Conventional metallic glasses are produced by rapid quenching of melts at cooling rates larger than 10^5 K s^{-1} . In contrast, the newly discovered BMGs can be produced at a typical cooling rate of 1 K s^{-1} such that large pieces of glassy materials can be obtained. Examples of such BMGs are the Zr-based and Pd-based quaternary and quinary alloys.^{3,4} Such BMGs exhibit excellent thermal stability making it experimentally possible to access the metallic supercooled liquid state down to the glass transition temperature (T_g). Clearly, BMGs possess unique thermodynamic and kinetic properties that hinder nucleation and growth in the supercooled liquid state. We will show how NMR can be used to obtain crucial information on the nature of atomic motions in the glassy and the supercooled liquid state of BMGs. Despite their different long-range orders,

metallic glasses and QC alloys could share some similarities in local structures. For instance, icosahedral clusters were proposed to be the local structure in some metallic glasses and supercooled liquids. Experimentally, upon thermal annealing BMGs were observed to form QC phases prior to crystallization.⁵

2 BASIC NMR CHARACTERISTICS IN QUASICRYSTALLINE ALLOYS

NMR studies of QC alloys were carried out immediately after the initial discovery.⁶ Structure, atomic motion, and electronic structures are the three main themes of most NMR studies of QC alloys. Lacking periodicity, the local environments in QC alloys are highly diversified despite the long-range translational and orientational orders. There exist a large number of nonequivalent atomic sites in QC alloys. As a result, the ^{27}Al NMR and NQR spectra measured in icosahedral Al-based QC alloys are broad and featureless. Based on ^{27}Al NQR spectra of i- $\text{Al}_{65}\text{Cu}_{23}\text{Fe}_{12}$ and i- $\text{Al}_{70}\text{Cu}_{15}\text{Ru}_{15}$ it was inferred that there exists a broad distribution of the magnitude of the EFG tensors associated with chemically nonequivalent Al sites.^{7,8} On single-grain i-AlPdMn samples, the angular dependence of ^{27}Al NMR spectra was investigated.^{8,9} In i- $\text{Al}_{70}\text{Pd}_{21.5}\text{Mn}_{8.5}$, the ^{27}Al NMR spectrum was found to be independent of the relative orientation between the static magnetic field (B_0) and the twofold rotation axis of the sample indicating a quasi-continuous distribution of structural environments.⁸ In i- $\text{Al}_{72.4}\text{Pd}_{20.5}\text{Mn}_{7.1}$, the ^{27}Al NMR spectrum was found to be slightly different at parallel and perpendicular orientations between B_0 and the five-fold rotation axis suggesting a large but finite number of physically nonequivalent atomic sites.⁹ A typical ^{27}Al NMR spectrum of Al-based QC alloys measured by the Hahn echo pulse sequence is shown in Figure 1. Powder pattern simulation of the $1/2 \leftrightarrow -1/2$ central transition at $B_0 = 9.4 \text{ T}$ shows that the quadrupole frequency $\nu_Q = 3\chi/2I(2I - 1)$ is on the order of 1.7 MHz in i- $\text{Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ (Figure 1),¹⁰ consistent with the NQR measurements.⁸ The isotropic shift is on the order of 150 ppm. Since the estimated second-order isotropic quadrupole shift $\delta_{\text{iso}}^{(2)}$ is around -70 ppm and the typical ^{27}Al chemical shift is between 0 and 200 ppm, the Knight shift K is on the order of 200 ppm or less which is much smaller than $K^{27\text{Al}}$ of 1600 ppm observed in Al metal.

NMR was used to study atomic motion in QC alloys. In i- $\text{Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$, a sharp increase of $1/T_1^{27\text{Al}}$ was measured above 673 K due to motion-induced quadrupole relaxation.¹⁰ The Arrhenius plot indicated a thermally activated process with activation energy of 0.48 eV. It is about three times smaller than that in corresponding crystalline alloys where vacancy-assisted diffusion dominates. This suggests that a different atomic transport process is at work in QC alloys at high temperature. ^{27}Al two-dimensional exchange NMR has been employed to measure atomic motion in i- $\text{Al}_{70}\text{Pd}_{21.4}\text{Re}_{8.6}$ below 130 K.¹¹ The mixing time dependence of the two-dimensional exchange spectrum suggests that the detected atomic motion is spatially confined in this temperature range, extending over only several inter-atomic distances and is attributed to a mode of local motion specifically related to quasicrystallinity.¹¹

Figure 1 (a), (b), and (c) are the ^{27}Al spectra of $i\text{-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ at various temperatures. The circles are the simulated spectrum of a powder-pattern of the anisotropic second-order quadrupole interaction convoluted with linewidth broadening. The dashed line is the quadrupole powder pattern ($\nu_Q = 1.7\text{ MHz}$, $\eta = 0$). (d) ^{27}Al spectrum of crystalline $\text{Al}_7\text{Cu}_2\text{Fe}$ at 973 K

3 PROBING ELECTRONIC STRUCTURES OF QUASICRYSTALLINE ALLOYS BY NMR

High-quality QC alloys exhibit remarkably different physical properties than typical metals, with poor electric and thermal conductivity and very small electric heat capacity.² The electric resistivity of a QC alloy increases as structural order increases in contrast to typical metals.² Furthermore, the electric resistivity increases with decreasing temperature.² In fact, some of the high-quality QC alloys were found to be in the proximity of metal-insulator transition.¹² These unusual physical properties are related to novel structures of the electronic density-of-states (DOS). It is well-established both theoretically and experimentally that a broad DOS pseudogap at E_F of about 0.5–1 eV in width exists in QC alloys caused by electron scattering at the almost spherical pseudo-Brillouin zone at the Fermi surface. The pseudogap was predicted to be enhanced¹³ by sp-d hybridization in Al-based QC alloys containing intermediate transition metals and plays a crucial role in the thermodynamic stability of QC phases. In addition, it was also predicted theoretically that a set of spiky DOS peaks of about 10 meV in width exist within the pseudogap as a result of strong hybridization between atomic orbitals in the presence of high local symmetry¹⁴ and hierarchical packing of icosahedral clusters.¹ The presence of such sharp feature at E_F will have a strong influence on the electric and thermal

properties of QC alloys. We will show how NMR can be used to detect and characterize such sharp DOS features at E_F .

3.1 Unusual Temperature Dependence of Nuclear Spin-Lattice Relaxation

Unlike in typical metallic alloys, the measured K and $1/T_1$ in QC alloys are very small. It indicates that the DOS at E_F , $g(E_F)$, of QC alloys is small compared to the calculated value based on free-electron model. However, some earlier NMR studies did not find evidence of sharp DOS features.^{15,16} Sharp features become noticeable as the quality of QC alloys improves. The NMR evidence of sharp DOS features is the unusual temperature dependence of $1/T_1$ that deviates substantially from the relation $1/T_1 \propto T$ observed in typical metallic systems. Figure 2 shows the nuclear spin-lattice relaxation (NSLR) curves of ^{27}Al measured in $i\text{-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$.¹⁷ Here, $M^*(t) = [M_0 - M(t)]/[M_0 - M(0)]$ is plotted¹⁷ as a function of the recovery time t scaled by T^2 . The NSLR curves measured between 100 and 600 K collapse into a single curve indicating that $1/T_1 \propto T^2$ (Figure 2). As discussed later, this novel temperature dependence is the signature of the sharp DOS valley at E_F . Similar temperature dependence of $1/T_1$ was also observed in other QC alloys including $i\text{-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ and $i\text{-Al}_{62.5}\text{Cu}_{24.5}\text{Fe}_{13}$,¹⁷ $i\text{-Al}_{70}\text{Pd}_{8.6}\text{Re}_{21.4}$,¹⁸ $i\text{-Al}_{70.5}\text{Pd}_{21}\text{Re}_{8.5}$, $i\text{-Al}_{62}\text{Cu}_{25.5}\text{Fe}_{12.5}$ and $i\text{-Al}_{72.4}\text{Pd}_{20.5}\text{Mn}_{7.1}$.¹⁹ At higher temperature above 600 K, $1/T_1$ is dominated by atomic motion-induced quadrupole relaxation.¹⁰ At low temperature below 20 K, $1/T_1^{27\text{Al}}T \propto T^{-0.69}$ was observed in $i\text{-Al}_{70}\text{Pd}_{8.6}\text{Re}_{21.4}$.¹⁸ This power law was described as a result of gradual real-space localization of the itinerant charge carriers. Similar low-temperature $1/T_1$ behaviors were also observed in $i\text{-Al}_{70.5}\text{Pd}_{21}\text{Re}_{8.5}$, $i\text{-Al}_{62}\text{Cu}_{25.5}\text{Fe}_{12.5}$, and $i\text{-Al}_{72.4}\text{Pd}_{20.5}\text{Mn}_{7.1}$.¹⁹ The low-temperature NMR results, consistent with the low-temperature electric conductivity, magnetoresistivity,¹² and magnetic susceptibility²⁰ measurements, indicate a strong effect of the weak localization and electron-electron interaction in high-quality QC alloys at low temperature.

Figure 2 The inversion recovery curves of the ^{27}Al nuclear magnetization M versus τ which is scaled by T^2 in $i\text{-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$. It shows that $1/T_1 \propto T^2$

3.2 The Mechanism of the Nuclear Spin-lattice Relaxation

In NMR studies of QC alloys, ^{27}Al , ^{63}Cu , and ^{65}Cu are the most frequently used isotopes. Two mechanisms can induce NSLR for these quadrupolar nuclei. One mechanism is the coupling between the nuclear spin and the unpaired conduction electron spins (magnetic relaxation). The second mechanism is the coupling of the nuclear electric quadrupole moment with the fluctuating EFG induced by atomic motions (quadrupolar relaxation). For magnetic relaxation, $1/T_1 \propto \gamma_n^2$; for quadrupolar relaxation, $1/T_1 \propto Q^2$. The relative contributions of the two mechanisms can be determined by measuring $1/T_1$ of a pair of proper isotopes. For i-AlCuRu and i-AlCuFe, ^{63}Cu and ^{65}Cu is such an excellent pair.¹⁷ $T_1^{65\text{Cu}}/T_1^{63\text{Cu}} = (\gamma_{63\text{Cu}}/\gamma_{65\text{Cu}})^2 = 0.87$ for magnetic relaxation and $T_1^{65\text{Cu}}/T_1^{63\text{Cu}} = (Q_{63\text{Cu}}/Q_{65\text{Cu}})^2 = 1.14$ for quadrupole relaxation. Figure 3 shows the ^{63}Cu and ^{65}Cu NSLR curves measured in i-Al₆₅Cu₂₀Ru₁₅ at 300 K and 9.4 T where $T_1^{65\text{Cu}}/T_1^{63\text{Cu}}$ was measured to be 0.83–0.90. In i-Al_{62.5}Cu_{24.5}Fe₁₃ $T_1^{65\text{Cu}}/T_1^{63\text{Cu}}$ was also measured to be 0.80–0.87.¹⁷ Thus, $1/T_1^{63\text{Cu}}$ and $1/T_1^{65\text{Cu}}$ in i-Al₆₅Cu₂₀Ru₁₅ and i-Al_{62.5}Cu_{24.5}Fe₁₃ are dominated by magnetic relaxation.¹⁷ In i-Al₆₅Cu₂₀Ru₁₅ $1/T_1^{27\text{Al}}$ was found¹⁷ to follow almost the same temperature dependence as $1/T_1^{63\text{Cu}}$. It suggests that the observed unusual temperature dependences of $1/T_1^{27\text{Al}}$, $1/T_1^{63\text{Cu}}$, and $1/T_1^{65\text{Cu}}$ are originated from the same mechanism through the coupling between the nuclear spins and unpaired conduction electron spins.

A strong field dependence of $1/T_1^{27\text{Al}}$ was observed in i-Al_{72.4}Pd_{20.5}Mn_{7.1}.²¹ The measured $1/T_1^{27\text{Al}}$ was ascribed to two components; one is independent of B_0 dominating at low temperature while the other is inversely proportional to B_0 dominating at high temperature.²¹ The origin of the second component remains unexplained.²¹ The nature of $1/T_1^{27\text{Al}}$ in other QCs were shown to be different. In i-Al₇₀Pd₂₀Re₁₀ and i-Al₆₅Cu₂₀Ru₁₅, $1/T_1^{27\text{Al}}$ was measured to be

field independent;²⁰ in i-Al₇₀Pd_{21.4}Re_{8.6} $1/T_1^{27\text{Al}}$ was measured to be field independent as well.¹⁸ Thus, the observed field dependence of $1/T_1^{27\text{Al}}$ in i-Al_{72.4}Pd_{20.5}Mn_{7.1} is not intrinsic to QC alloys. In Al-based QC alloys with intermediate transition metals, NMR results could be complicated by possible localized magnetic moments at the atomic sites of the transition metals. Thus, the field dependence of $1/T_1^{27\text{Al}}$ in i-AlPdMn might be related to localized magnetic moments since the magnetic moment concentration in i-AlPdMn is several orders of magnitude larger than in i-AlPdRe and i-AlCuRu according to magnetic susceptibility measurement.²⁰ In view of this, i-AlPdRe and i-AlCuRu are more appropriate systems for NMR study of the intrinsic electronic properties of QC alloys.

3.3 The Sharp DOS Feature

As discussed in Section 3.1, below 20 K the measured T_1 in i-Al₇₀Pd_{8.6}Re_{21.4} are found to be associated with the electron-electron interaction and weak localization. Above 600 K, T_1 is dominated by the contribution of atomic motion. Therefore, only T_1 measured in the intermediate temperature range, which is governed by the coupling between the nuclear spins and the unpaired independent conduction electron spins, will be used to extract the sharp DOS feature at E_F . In this section, we discuss the derivation of the sharp DOS feature by analyzing the NMR results measured in this temperature range.

In Al-based QCs with intermediate transition metals such as i-AlPdRe and i-AlCuRu, the Al 3s and 3p-bands are strongly hybridized with the Re 5d-band and the Ru 4d-band, respectively. The K and $1/T_1$ of ^{27}Al , ^{63}Cu and ^{65}Cu are dominated by the Fermi-contact interaction with the conduction 3s-electron spins and the core-polarization induced by the conduction d electron spins. Denoting the partial DOS of the 3s and d-bands as $g_s(E)$ and $g_d(E)$, respectively, K is described by

$$K = \frac{1}{k_B T} \int [\alpha_s g_s(E) + \alpha_d g_d(E)] f(E) [1 - f(E)] dE, \quad (1)$$

where $f(E)$ is the Fermi-Dirac distribution function, $\alpha_s = \frac{4\pi}{3} \hbar^2 \gamma_e^2 \langle |u_k^2(0)| \rangle_{E_F}$ where γ_e is the electronic gyromagnetic ratio and $\langle |u_k^2(0)| \rangle_{E_F}$ is the density of the 3s-band wave function at the Al nucleus averaged over the Fermi surface, α_d is associated with the core-polarization by the d-bands and is negative. $1/T_1$ is described by

$$\frac{1}{T_1} = \int [\beta_s g_s^2(E) + \beta_d g_d^2(E)] f(E) [1 - f(E)] dE, \quad (2)$$

where $\beta_s = 4\pi \hbar \gamma_n^2 \alpha_s^2$ and $\beta_d = 4\pi p \hbar \gamma_n^2 \alpha_d^2$ (p is a factor related to the local symmetry and degeneration of the d-bands).²²

Since $f(E)[1 - f(E)]$ vanishes quickly as E deviates from E_F by a few $k_B T$, the temperature dependence of K and $1/T_1$ are determined by DOS near E_F . In typical metallic systems, since the DOS variation over several $k_B T$ is small near E_F , K is temperature independent and $1/T_1 \propto T$. In high quality QC alloys, however, novel temperature dependences of K and $1/T_1$ were observed inferring a sharp DOS feature near E_F . For Al-based QC alloys containing intermediate transition metals,

Figure 3 The ^{63}Cu and ^{65}Cu NSLR curves in i-Al₆₅Cu₂₀Ru₁₅ at 300 K and 9.4 T. The curve for ^{63}Cu is plotted as $M^*(0.87t)$. It shows that $T_1^{65\text{Cu}}/T_1^{63\text{Cu}}$ is 0.83–0.90

Figure 4 $1/T_1^{27\text{Al}}$ versus T in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$. The solid line is a fit with equation (5)

the theoretical calculations indicated¹³ an enhanced pseudogap at E_F by sp-d hybridization leading to a sharp DOS valley. The structures of the partial DOS $g_s(E)$ and $g_d(E)$ within the sharp DOS valley near E_F can be assumed as

$$\begin{aligned} g_s(E) &= g_{0s} + g_{1s}|E - E_F|^\varepsilon, \\ g_d(E) &= g_{0d} + g_{1d}|E - E_F|^\varepsilon \end{aligned} \quad (3)$$

with g_{0s} and g_{0d} as the residual DOS at E_F for 3s-band and d-bands, respectively.

K is obtained from equations (1) and (3) as

$$K = (\alpha_s g_{0s} + \alpha_d g_{0d}) + 2C(\varepsilon)(\alpha_s g_{1s} + \alpha_d g_{1d})(k_B T)^\varepsilon, \quad (4)$$

where $C(\varepsilon) = \int_0^\infty x^\varepsilon e^x / (1 + e^x)^2 dx$. Using equations (2) and (3), $1/T_1$ is obtained as

$$\begin{aligned} \frac{1}{T_1} &= k_B T [(\beta_s g_{0s}^2 + \beta_{ds} g_{0d}^2) + 4C(\varepsilon)(\beta_s g_{0s} g_{1s} + \beta_{ds} g_{0d} g_{1d})(k_B T)^\varepsilon \\ &\quad + 2C(2\varepsilon)(\beta_s g_{1s}^2 + \beta_{ds} g_{1d}^2)(k_B T)^{2\varepsilon}]. \end{aligned} \quad (5)$$

At low temperature, equations (4) and (5) lead to the conventional temperature dependences where K is temperature independent and $1/T_1 \propto T$. As discussed above, however, equations (4) and (5) are not suitable for analyzing the low temperature K and $1/T_1$ data in QC alloys since the electron-electron interaction and weak localization are not included. At higher temperatures, equations (4) and (5) lead to $K \propto T^\varepsilon$ and $1/T_1 \propto T^{1+2\varepsilon}$. The power law $1/T_1 \propto T^2$ was observed in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$ and $\text{i-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ above 100 K suggesting that $\varepsilon = 1/2$.¹⁷ Indeed, the fit of $1/T_1^{27\text{Al}}$ by equation (5) shows that $\varepsilon \approx 1/2$ (Figure 4). Since $1/T_1 \propto T^2$ is induced by the sharp DOS valley and is clearly obeyed up to 400 K, the width of the $\varepsilon = 1/2$ region in the sharp DOS valley should be at least as large as 25 meV.¹⁷ The measured small residual $g(E)$ at E_F in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$ and $\text{i-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$ agrees with the heat capacity measurements.¹⁷ Since the NMR results at much higher temperature are complicated by atomic motion,¹⁰ the DOS shape further away from E_F cannot be determined by NMR.

For $\varepsilon = 1/2$, equation (4) leads to a weak temperature dependence of K at high temperature. Indeed, $K^{27\text{Al}}$ was measured to follow such a weak temperature dependence in $\text{i-Al}_{70}\text{Pd}_{20}\text{Re}_{10}$ and $\text{i-Al}_{65}\text{Cu}_{20}\text{Ru}_{15}$.^{10,17} Moreover, the measured temperature dependence of $K^{27\text{Al}}$ was found¹⁷ to be correlated with that of $1/T_1^{27\text{Al}}$ as described by equations (4) and (5). The analysis of the temperature dependences of $K^{27\text{Al}}$ and $1/T_1^{27\text{Al}}$ indicate a strong effect of the core-polarization at Al sites that is consistent with the theoretical prediction of the strong sp-d hybridization in Al-based QC alloys containing intermediate transition metals.¹²

3.4 Comments on the Approximation Method Based on Taylor Expansion

An approximation method was used to describe the DOS variation near E_F for narrow d-bands and analyze the non-linear temperature dependence of $1/T_1$ and the temperature dependence of K such as in Pt metal.²² A similar approximation was used to analyze the nonlinear temperature dependence of $1/T_1$ in QC alloys.^{10,19,21} Here we show that such approximation can often be insufficient and misleading in analyzing the effect of the DOS variation near E_F .

The approximation is based on the Taylor expansion of $g(E)$ at E_F (E_F at $T = 0$) as

$$\begin{aligned} g(E) &= g(E_F^0) + (E - E_F^0)g'(E_F^0) \\ &\quad + \frac{1}{2}(E - E_F^0)^2 g''(E_F^0), \end{aligned} \quad (6)$$

with $g'(E_F^0)$ and $g''(E_F^0)$ as the first and second derivatives of $g(E)$ to E at E_F^0 , respectively. Because of the second term in equation (6), E_F could be temperature dependent if $g(E)$ is not symmetric about E_F^0 . Define $\Delta E_F = E_F - E_F^0$, equation (6) can be rewritten as

$$\begin{aligned} g(E) &= [g(E_F^0) + \Delta E_F g'(E_F^0) + \frac{1}{2}(\Delta E_F)^2 g''(E_F^0)] \\ &\quad + (E - E_F)[g'(E_F^0) + \Delta E_F g''(E_F^0)] \\ &\quad + \frac{1}{2}(E - E_F)^2 g''(E_F^0). \end{aligned} \quad (7)$$

Using equation (7) and the conservation of electron density described by $\frac{d}{dT} [\int g(E) f(E) dE] = 0$, it is straightforward to obtain

$$\begin{aligned} \frac{d(\Delta E_F)}{dT} &\left[g(E_F^0) + \Delta E_F g'(E_F^0) + \frac{1}{2}(\Delta E_F)^2 g''(E_F^0) \right. \\ &\quad \left. + \frac{\pi^2}{6} g''(E_F^0)(k_B T)^2 \right] \\ &= -\frac{\pi^2}{3} [g'(E_F^0) + \Delta E_F g''(E_F^0)] k_B^2 T. \end{aligned} \quad (8)$$

The derivatives of ΔE_F with T can be derived from equation (8) and the Taylor expansion of E_F can be calculated at $T = 0$ as

$$\begin{aligned} E_F &= E_F^0 - \frac{\pi^2}{6} (k_B T)^2 \frac{g'(E_F^0)}{g(E_F^0)} + \frac{\pi^4}{72} (k_B T)^4 \frac{g'(E_F^0)}{g(E_F^0)} \\ &\quad \times \left[2 \frac{g''(E_F^0)}{g(E_F^0)} - \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] + O(T^6). \end{aligned} \quad (9)$$

For a symmetric $g(E)$ about $E = E_F^0$, $g'(E_F^0) = 0$ and E_F is temperature independent.

Using equations (1), (7), and (9), K can be calculated to the order of T^5 as

$$K \propto g(E_F^0) \left\{ 1 + \frac{\pi^2}{6} (k_B T)^2 \left[\frac{g''(E_F^0)}{g(E_F^0)} - \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] + \frac{\pi^6}{60} (k_B T)^4 \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \left[3 \frac{g''(E_F^0)}{g(E_F^0)} - \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] \right\} + 0(T^6). \quad (10)$$

Using equations (2), (7), and (9), the calculated $1/T_1$ is given by

$$\frac{1}{T_1} \propto g^2(E_F^0) \left\{ k_B T + \frac{\pi^2}{3} (k_B T)^3 \frac{g''(E_F^0)}{g(E_F^0)} + \frac{\pi^6}{60} (k_B T)^5 \frac{g''(E_F^0)}{g(E_F^0)} \left[7 \frac{g''(E_F^0)}{g(E_F^0)} - 5 \left(\frac{g'(E_F^0)}{g(E_F^0)} \right)^2 \right] \right\} + 0(T^7). \quad (11)$$

As an approximation, equations (9), (10), and (11) are valid only if the second terms on the right hand side of these equations are much smaller than the corresponding first terms. This is exactly what was assumed in Refs.^{10,19,21,22} in which only the first and second terms of these equations were included in the approximation. There, the measured $1/T_1$ in QC alloys were fitted with only the T and T^3 terms.^{10,19,21} However, the fits of the $1/T_1$ data indicated that the contribution of the T^3 term is comparable or even larger than that of the T term within the investigated temperature range. In this case, equation (11) shows that the contribution of the T^5 term cannot be neglected and the expansion itself may not converge. Moreover, K should be dominated by the contribution of the T^2 and T^4 terms. Thus, the approximation implies a strong temperature dependence of K , in contrast to the observation of a weak temperature dependence of K .^{10,17} Thus, the approximation is not valid for analyzing the measured $1/T_1$ in QC alloys. In general, it is not valid to use this approximation method to analyze $1/T_1$ that deviates significantly from $1/T_1 \propto T$.

4 THE ALIGNMENT ECHO TECHNIQUE FOR $I \geq 1$

NMR has made important contributions to the study of atomic and molecular motion in amorphous systems. However, NMR was rarely used to measure atomic motion in metallic glasses and metallic supercooled liquids, especially slow atomic motion. The reasons are twofold. First, the fast rate of crystallization upon heating in conventional metallic glasses and supercooled liquids does not allow sufficient time for most experimental approaches including NMR. Secondly, the longest timescale of atomic motion detectable by NMR is intrinsically limited by T_1 that is very short in typical metallic systems. Since BMGs exhibit excellent glass formability and remarkable thermal stability, a large temperature range becomes accessible for NMR up to temperatures significantly above T_g . This allows the experimental studies of the nature of

glass transition and the nature of atomic motion in the supercooled liquid state near T_g . It was fortunate for NMR studies that the representative BMGs, $\text{Zr}_{41.5}\text{Ti}_{22.5}\text{Cu}_{22.5}\text{Ni}_{10}\text{Be}_{22.5}$ (vit1) and $\text{Zr}_{41.5}\text{Ti}_{22.5}\text{Cu}_{22.5}\text{Ni}_{10}\text{Be}_{27.5}$ (vit4), contain Be where T_1^{Be} is very long. This makes NMR detection of slow atomic motion feasible in both the glassy and deeply supercooled liquid states.^{23–25}

The nuclear spin alignment echo technique (SAE) of ^2H ($I = 1$) has been used extensively for studying motion in polymers.²⁶ This technique was extended to the case of $I = 3/2$ in the study of translational atomic motion in BMGs using ^9Be NMR.^{23–25} Later, ^7Li SAE was used in measuring ionic motion in electrolyte materials.²⁷ The ^2H SAE technique was described extensively in the literature.²⁶ A general treatment was given recently for $I = 1$ to $9/2$.²³ Following the latter, assume that the truncated Hamiltonian of a nuclear spin system in the rotating frame consists of the Zeeman interaction (due to resonance off-set) and first-order electric quadrupole interaction given by

$$\hat{H} = \beta \hat{I}_z + \alpha (3\hat{I}_z^2 - \hat{I}^2) \quad (12)$$

where β is the shift relative to the rf frequency, α is proportional to the quadrupole resonance frequency.

The pulse sequence of SAE, $90^\circ - \tau_1 - \theta_\phi - t - \theta_{\phi'} - \tau_2 -$, is applied with nonselective RF pulses with the time parameters chosen such that $\tau_1 < T_2 < t$. θ and θ' are the flipping angles of the second and third pulses, respectively, with ϕ and ϕ' as the corresponding phases with respect to the first pulse. Since atomic motion could occur during the diffusion time t , the values of α and β associated with a given nuclear spin during the time interval τ_1 are denoted as α_1 and β_1 , respectively, and as α_2 and β_2 , respectively, during the time interval τ_2 . Since $t > T_2$, the spin density operator during t evolves into a diagonal density operator ($\hat{\rho}(t)$) represented by a linear combination of various nuclear spin orders (from the Zeeman order to $2I$ -th-rank spin order). The k th-rank spin order is proportional to the k th-rank zeroth-order irreducible tensor $A^{(k,0)}$ (see Table 1 in Ref.²³ for the explicit expressions of $A^{(k,0)}$ for $I = 1/2$ to $9/2$). The signal appearing after the third pulse is given by²³

$$S(\tau) = -\cos \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} \sum_{\text{oddk}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2) + i \sin \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} \sum_{\text{evenk}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2), \quad (13)$$

where $\phi_{\text{eff1}} = \phi + \beta_1 \tau_1$, $\phi_{\text{eff2}} = \phi' + \beta_2 \tau_2$, and $f_k(\theta, \alpha \tau)$ is the coefficient given by

$$f_k(\theta, \alpha \tau) = \text{Trace}(e^{-i\theta I_y} e^{-3i\alpha I_z^2 \tau} \hat{I}_x e^{3i\alpha I_z^2 \tau} e^{i\theta I_y} A^{(k,0)}) \quad (\text{odd } k) \\ f_k(\theta, \alpha \tau) = \text{Trace}(e^{-i\theta I_y} e^{-3i\alpha I_z^2 \tau} \hat{I}_y e^{3i\alpha I_z^2 \tau} e^{i\theta I_y} A^{(k,0)}) \quad (\text{even } k). \quad (14)$$

Thus, $f_k(\theta, \alpha_1 \tau_1)$ is the coefficient of the k th-rank nuclear spin order during t . For example, $f_1(\theta, \alpha_1 \tau_1)$ and $f_2(\theta, \alpha_1 \tau_1)$ correspond to the Zeeman and quadrupole order, respectively. It is of note that $\cos \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2)$ (odd k) and $\sin \phi_{\text{eff1}} e^{i\phi_{\text{eff2}}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2)$ (even k) are single-particle correlation functions connecting the local environments experienced by a nuclear spin during τ_1 and τ_2 .

For an ensemble of nuclear spins, an alignment echo forms at $\tau_2 = \tau_1$ if no motion occurs during t . On the other hand, atomic motion may induce the change of the local environments and destroy the single-particle correlation leading to the alignment echo decay. The k th-rank nuclear spin order created during t could decay as well during t with a decay rate of W_k induced by the NSLR mechanisms. Thus, following equation (13) the SAE echo height is described by

$$S_{\text{echo}}(t) = - \sum_{\text{oddk}} e^{-W_k t} \langle \cos \phi_{\text{eff}1} e^{i\phi_{\text{eff}2}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2) \rangle \\ + i \sum_{\text{evenk}} e^{-W_k t} \langle \sin \phi_{\text{eff}1} e^{i\phi_{\text{eff}2}} f_k(\theta, \alpha_1 \tau_1) f_k(\theta', -\alpha_2 \tau_2) \rangle \quad (15)$$

with $\langle \rangle$ denoting the ensemble average. In metallic glasses, NSLR is usually dominated by the coupling between the nuclear spins and unpaired conduction electron spins. In this case, the evolution of $\hat{\rho}(t)$ can be described by:

$$\frac{d\hat{\rho}(t)}{dt} = J_1 [[\hat{\rho}(t) - \hat{\rho}_0, \hat{I}_+], \hat{I}_-], \quad (16)$$

with J_1 as a constant related to the magnetic properties of the spin system and $\hat{\rho}_0$ as the density operator at thermal equilibrium. Using the following identity

$$[[A^{(k,0)}, \hat{I}_+], \hat{I}_-] = k(k+1)A^{(k,0)}, \quad (17)$$

it is straightforward to obtain $\hat{\rho}(t)$ as

$$\hat{\rho}(t) = \hat{\rho}_0 + \sum_{k=0}^{2I} C_k e^{-k(k+1)t/2T_1} A^{(k,0)} \quad (18)$$

with C_k as the coefficients. Thus, $W_k = k(k+1)/2T_1$ which is true for other magnetic relaxation mechanisms as well. Since W_k varies with k , it is easier to extract the information about motion when only singular rank of nuclear spin order is created during t . In this case the $e^{-W_k t}$ factor of the chosen rank can be easily separated from the motion-related single-particle correlation functions by measuring T_1 .

In the presence of both a α distribution $\delta\alpha$ and a β distribution $\delta\beta$, it is in general difficult to produce a singular rank of spin order. If $\delta\beta \ll \delta\alpha$, τ_1 can be chosen such that $\delta\beta\tau_1 \ll \pi/2 \ll \delta\alpha\tau_1$. Then, odd-ranked spin orders can be created separately from even-ranked spin orders by choosing $\phi = 0^\circ$ (180°) for creating odd-ranked spin orders and $\phi = 90^\circ$ (270°) for creating even-ranked spin orders. Therefore, by selecting proper ϕ it is possible to produce pure Zeeman order or quadrupole order for $I = 1$. For $I = 3/2$, pure quadrupole order can be produced by choosing $\phi = 90^\circ$ (270°). On the other hand, the Zeeman order and octupole order cannot be separated. Equation (15) shows that the contribution of certain undesired nuclear spin orders can be suppressed also by the choice of the θ or θ' values based on the value of $f_k(\theta, \alpha\tau)$.

In Ref.²³ $f_k(\theta, \alpha\tau)$ ($k = 1, 2, \dots, 2I$) were derived explicitly based on the equation

$$e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm e^{i\alpha\hat{I}_z^n} = \hat{I}_\pm [1 \quad \cos 2\alpha \quad \dots \quad \cos(2I-1)\alpha] \\ \times \begin{bmatrix} 1 & 1 & \dots & 1 \\ 0 & 2^2 & \dots & (2I-1)^2 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 2^{2I-1} & \dots & (2I-1)^{2I-1} \end{bmatrix} \begin{bmatrix} 1 \\ (1 \pm 2\hat{I}_z)^2 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-1} \end{bmatrix} \\ - i\hat{I}_\pm [\sin 2\alpha \quad \sin 4\alpha \quad \dots \quad \sin(2I-1)\alpha] \\ \times \begin{bmatrix} 2 & 4 & \dots & (2I-1) \\ 2^3 & 4^3 & \dots & (2I-1)^3 \\ \vdots & \vdots & \ddots & \vdots \\ 2^{2I-2} & 4^{2I-2} & \dots & (2I-1)^{2I-2} \end{bmatrix} \begin{bmatrix} (1 \pm 2\hat{I}_z) \\ (1 \pm 2\hat{I}_z)^3 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-2} \end{bmatrix} \quad (19)$$

for half-integer I ($I = 3/2, 5/2, 7/2, 9/2$) and on the equation

$$e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm e^{i\alpha\hat{I}_z^n} = \hat{I}_\pm [\cos \alpha \quad \cos 3\alpha \quad \dots \quad \cos(2I-1)\alpha] \\ \times \begin{bmatrix} 1 & 1 & \dots & 1 \\ 1 & 3^2 & \dots & (2I-1)^2 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 3^{2I-2} & \dots & (2I-1)^{2I-2} \end{bmatrix} \\ \times \begin{bmatrix} 1 \\ (1 \pm 2\hat{I}_z)^2 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-2} \end{bmatrix} \\ - i\hat{I}_\pm [\sin \alpha \quad \sin 3\alpha \quad \dots \quad \sin(2I-1)\alpha] \\ \times \begin{bmatrix} 1 & 3 & \dots & (2I-1) \\ 1 & 3^3 & \dots & (2I-1)^3 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 3^{2I-1} & \dots & (2I-1)^{2I-1} \end{bmatrix} \begin{bmatrix} (1 \pm 2\hat{I}_z) \\ (1 \pm 2\hat{I}_z)^3 \\ \vdots \\ (1 \pm 2\hat{I}_z)^{2I-1} \end{bmatrix} \quad (20)$$

for integer I ($I = 1, 3$). It is interesting to note that by using

$$e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm^n e^{i\alpha\hat{I}_z^n} = e^{-in(n-1)\alpha} \hat{I}_\pm^{n-1} (e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm e^{i\alpha\hat{I}_z^n}) \quad (21)$$

and equations (19) and (20), a general formula for $e^{-i\alpha\hat{I}_z^n} \hat{I}_\pm^n e^{i\alpha\hat{I}_z^n}$ can be easily obtained.

For $I = 1$, $f_k(\theta, \alpha\tau)$ are given by

$$f_1(\theta, \alpha\tau) = -\sqrt{2} \sin \theta \cos 3\alpha\tau; \\ f_2(\theta, \alpha\tau) = \sqrt{\frac{3}{2}} \sin 2\theta \sin 3\alpha\tau. \quad (22)$$

Both $f_1(\theta, \alpha\tau)$ and $f_2(\theta, \alpha\tau)$ are suitable for detecting motion, although the maximized signal from $f_1(\theta, \alpha\tau)$ (Zeeman order) is larger. For $I = 3/2$,

$$f_1(\theta, \alpha\tau) = -\frac{1}{\sqrt{5}} \sin \theta (2 + 3 \cos 6\alpha\tau); \\ f_2(\theta, \alpha\tau) = -\frac{3}{2} \sin 2\theta \sin 6\alpha\tau; \\ f_3(\theta, \alpha\tau) = -\frac{3}{2\sqrt{5}} \sin \theta (5 \cos^2 \theta - 1)(1 - \cos 6\alpha\tau). \quad (23)$$

It is possible to create a pure Zeeman order by choosing $\phi = 0^\circ$ (180°) and $5 \cos^2 \theta = 1$ or $5 \cos^2 \theta' = 1$. In this case

$$S_{\text{echo}}(t) \propto e^{-t/T_1} \langle f_1(\theta, \alpha_1 \tau_1) f_1(\theta', -\alpha_2 \tau_2) \rangle \propto 4e^{-t/T_1} + \frac{9}{2} e^{-t/T_1} \langle \cos 6(\alpha_1 - \alpha_2) \tau_1 \rangle \quad (24)$$

Since motion affects the second term but not the first, almost half the resonance signal does not change after motion. Thus, the existence of two terms with different decay rates complicates the analysis. On the other hand, a pure quadrupole order can be created by choosing $\phi = 90^\circ$ (270°). Then, the SAE echo height is given by

$$S_{\text{echo}}(t) \propto \frac{9}{8} e^{i\phi'} e^{-W_2 t} \sin 2\theta \sin 2\theta' \langle \cos 6(\alpha_1 - \alpha_2) \tau_1 \rangle. \quad (25)$$

The signal is maximized at $\theta = \theta' = 45^\circ$. For $I = 5/2$,

$$\begin{aligned} f_1(\theta, \alpha\tau) &= -\frac{1}{\sqrt{70}}(9 + 16 \cos 6\alpha\tau + 10 \cos 12\alpha\tau) \sin \theta; \\ f_2(\theta, \alpha\tau) &= \frac{\sqrt{3}}{2\sqrt{7}}(4 \sin 6\alpha\tau + 5 \sin 12\alpha\tau) \sin 2\theta; \\ f_3(\theta, \alpha\tau) &= -\frac{1}{2\sqrt{5}}(-3 - 2 \cos 6\alpha\tau + 5 \cos 12\alpha\tau) \\ &\quad \times \sin \theta (5 \cos^2 \theta - 1); \\ f_4(\theta, \alpha\tau) &= \frac{5}{8\sqrt{7}}(-2 \sin 6\alpha\tau + \sin 12\alpha\tau) \sin 2\theta (1 + 7 \cos 2\theta); \\ f_5(\theta, \alpha\tau) &= -\frac{5}{64\sqrt{7}}(3 - 4 \cos 6\alpha\tau + 12 \cos 12\alpha\tau) \\ &\quad \times \sin \theta (15 + 28 \cos \theta + 21 \cos 4\theta). \end{aligned} \quad (26)$$

All $f_k(\theta, \alpha\tau)$ associated with odd-ranked nuclear spin orders contain a constant term as well as motion-related terms. As discussed above, this complicates the analysis when measuring the single-particle correlation functions of these spin orders. On the other hand, by choosing $\phi = 90^\circ$ (270°) and $1 + 7 \cos 2\theta = 0$ or $1 + 7 \cos 2\theta' = 0$, a pure quadrupole order can be created. The SAE echo height is then given by

$$S_{\text{echo}}(t) \propto \frac{6}{7} e^{i\phi'} e^{-W_2 t} \sin 2\theta' \sin 2\theta' \times \left\langle \cos 6(\alpha_1 - \alpha_2) \tau_1 + \frac{25}{16} \cos 12(\alpha_1 - \alpha_2) \tau_1 \right\rangle \quad (27)$$

5 DETECTION OF SLOW ATOMIC MOTION IN BULK METALLIC GLASSES BY NMR OF ^9Be

The ^9Be spectra of vit1 and vit4 consist of a narrow central line and a broad line (Figure 5). The broad line, with a field-independent $\Delta\nu_{1/2}$ of (100 ± 10) kHz, is associated with the satellite transitions ($3/2 \leftrightarrow 1/2$ and $-1/2 \leftrightarrow -3/2$) broadened by the first order quadrupole interaction. The central line, with $\Delta\nu_{1/2}$ as (6.1 ± 0.2) kHz at 9.4 T and (3.6 ± 0.1) kHz at 4.7 T, is associated with the central transition ($1/2 \leftrightarrow -1/2$) broadened by the Zeeman interaction distribution. The $K^{9\text{Be}}$ is negligible and $T_2^{9\text{Be}}$ about 1.5 ms.²⁴ Dominated by Korringa relaxation, $1/T_1^{9\text{Be}}$ is²⁴ proportional to T with

Figure 5 The ^9Be spectra of vit1 at 9.4 T. The broad line is shown more clearly by expanding the vertical scale by a factor of 3

$(TT_1)^{-1} = 0.00105 \text{ K}^{-1} \text{ s}^{-1}$. According to equation (18), the decay rate of the ^9Be quadrupole order is $3/T_1$ as demonstrated experimentally.²³

The ^9Be SAE pulse sequence is: $90_x^0 - \tau_1 - 45_{\phi'}^0 - t - 45_{\phi'}^0 - \tau_2 -$ with a short τ_1 ($6 - 15 \mu\text{s}$) to create a pure quadrupole order. Following equation (26), the SAE echo height is proportional to $f(t) = \langle \cos(\omega_1 - \omega_2) \tau_1 \rangle e^{-3t/T_1}$. $\omega_1 = 6\alpha_1$ and $\omega_2 = 6\alpha_2$, varying over a range of $2\pi \times 100$ kHz in vit1 and vit4, are determined by the truncated quadrupole interactions experienced by the spin during τ_1 and τ_2 , respectively. The featureless broad line shown in Figure 5 indicates that the characteristic powder pattern of the observed ^9Be spectrum in Be metal is smeared out in vit1 and vit4. It suggests a random distribution of quadrupole interaction, which is crucial for SAE to be effective in detecting motion. In glasses and supercooled liquids, the quadrupole interaction with respect to B_0 differs from site to site because of the disordered structure. Thus, single-atom jumps are expected to change ω randomly within its range which induces a reduction of $f(t)$. On the other hand, SAE is not sensitive to collective motion since the quadrupole interactions at Be sites change very little under collective translational motion involving Be atoms and most of their nearest neighbors. Also, SAE is not sensitive to restricted collective rotational motion with small rotation angle because $|(\omega_1 - \omega_2)|\tau_1 \ll 1$.

Fast data acquisition is crucial for studying thermal dynamics in metastable materials such as metallic supercooled liquids. In Refs.^{24,25} the pulse-spin locking technique was used to improve S/N. Following the ^9Be SAE pulse sequence, a train of 90° pulses are applied; the full sequence is $90_x^0 - \tau_1 - 45_{\phi'}^0 - t - 45_{\phi'}^0 - 2\tau_1 - 90_{\phi'}^0 - 2\tau_1 - 90_{\phi'}^0 - \dots - 90_{\phi'}^0 -$. Here, a train of echoes with the same origin and feature as the first alignment echo are detected and all echoes are accordingly summed up. The full sequence for measuring $1/T_1$, using the saturation recovery method with a comb and quadrupole echo detection sequence, is 'comb' - $t - 90_x^0 - \tau - 90_{\pm y}^0 - 2\tau - 90_{\pm y}^0 - 2\tau - 90_{\pm y}^0 \dots - 90_{\pm y}^0 -$. Using pulse-spin locking,

Figure 6 The temperature dependence of the atomic jump rate Ω and the diffusivity D in vit1 and vit4. D (scale on the right) and Ω (scale on the left) are plotted versus $1000/T$. A kink at 620 K, which is around T_g , is observed in the $D(T)$ curves in both vit1 and vit4. This kink is absent in the $\Omega(T)$ curves that follow the same Arrhenius behavior in both the supercooled liquid and glassy state

each ^9Be SAE decay curve and $1/T_1$ can be measured in several minutes. This enables the isothermal annealing study and the first NMR study in supercooled metallic liquids.

The ^9Be SAE echo decay curve measured at 620 K is shown in Figure 6 that is fitted by a single-exponential function $f(t) = e^{-t/T_{QE}}$. Such behavior is expected for atomic motion causing random changes of ω , where $1/T_{QE} = 3/T_1 + \Omega$ with Ω as the atomic jump rate. The observed single-exponential decay is inconsistent with constrained jumps between neighboring sites such as double-well potentials. It is consistent with unconstrained Be hopping assisted by thermal fluctuation of spread-out free volume.²⁴ In vit1 and vit4, the measured Ω follows Arrhenius behavior $\Omega(T) = \Omega_0 e^{-E_a/k_B T}$ with the fitted activation energy $E_a = (1.2 \pm 0.15) \text{ eV}$. Below 620 K, no annealing-time dependence of Ω is observed by SAE indicating that the measured Ω is intrinsic for the glassy state. The SAE measurements inferred that the Be diffusion process is via single-atom hopping.²⁴ In deeply supercooled liquids, the combine SAE and diffusion measurements indicated that two diffusion processes contribute to the long-range Be transport.²⁵ One is single-atom hopping. The other process is collective motion involving most of the nearest neighbors of Be atoms.

1 INTRODUCTION

Conventional methods of crystal structure determination such as X-ray and neutron scattering yield the unit cell structure averaged over space and time. While the knowledge of such a space and time averaged structure is sufficient in most systems this is not the case in inhomogeneous- or order-disorder-type ferroelectrics and proton glasses where local deviations from the averaged structure determine the specific properties of these systems. 1D and 2D NMR of nuclei with a nonzero quadrupole coupling or chemical shift tensor interaction as well as NQR provide here a unique tool for the determination of the local atomic structure and dynamics which is unobtainable by other techniques.

In the fast motion regime, $\omega\tau \ll 1$, the nucleus at site i ‘sees’ the time averaged value of the quadrupole coupling or chemical shift tensor interaction so that¹

$$\omega_i = \omega_0 + \omega_1 \langle \eta_i \rangle; \quad \langle \eta_i \rangle \neq 0 \quad T < T_c \quad (1a)$$

whereas

$$\omega_i = \omega_0; \quad \langle \eta_i \rangle = 0 \quad T > T_c \quad (1b)$$

Here $\langle \eta_i \rangle$ is the time averaged value of the long-range order parameter at site i . It is $\langle \eta_i \rangle$ which is zero above T_c and non-zero below T_c .

Close to the phase transition temperature T_c , the spin-lattice relaxation rate will be determined by the order parameter fluctuations¹

$$T_1^{-1} \propto \sum_{\mathbf{q}} \int_{-\infty}^{\infty} \langle \delta \eta(\mathbf{q}, 0) \delta \eta(\mathbf{q}, t) \rangle e^{i\omega t} dt \quad (2a)$$

where $\delta \eta(\mathbf{q}, t) = \eta(\mathbf{q}, t) - \langle \eta(\mathbf{q}, t) \rangle$ and $\langle \dots \rangle$ denotes the ensemble average.

Applying the fluctuation dissipation theorem, equation (3) can be rewritten as¹

$$T_1^{-1} \propto \sum_{\mathbf{q}} \frac{\chi(\mathbf{q}, 0) \tau(\mathbf{q})}{1 + \omega^2 \tau(\mathbf{q})^2} \quad (2b)$$

where $\chi(\mathbf{q}, 0)$ is the wave vector dependent static susceptibility of the order parameter and $\tau(\mathbf{q})$ is the corresponding wave vector dependent correlation time.¹ For the Ising model one finds

$$\chi(\mathbf{q}) = \frac{\chi(\mathbf{q} = 0, 0)}{1 + \mathbf{q}^2 \xi^2} \quad (3a)$$

and

$$\tau(\mathbf{q}) = \frac{\tau(\mathbf{q} = 0)}{1 + \mathbf{q}^2 \xi^2} \quad (3b)$$

where

$$\tau(\mathbf{q} = 0) \propto \chi(\mathbf{q} = 0) \propto \frac{C}{T - T_c}; \quad T > T_c \quad (3c)$$

and ξ is the correlation length, which diverges at T_c . In the limit $\omega\tau \ll 1$ T_1^{-1} thus exhibits a critical behavior near T_c , while for $\omega\tau \gg 1$ T_1^{-1} should stay nearly constant. Another point to be stressed is that in the slow motion regime the nucleus ‘sees’ the instantaneous value of the order parameter and not the time averaged value.

2 INHOMOGENEOUS FERROELECTRICS AND PROTON GLASSES

Ferroelectric and antiferroelectric phase transitions¹ are characterized by:

1. the breaking of a discrete symmetry group at the paraelectric to ferroelectric or antiferroelectric transition;
2. the appearance of a long-range order parameter below T_c —the spontaneous polarization P in ferroelectrics or the sublattice polarization $P_a = -P_b$ in antiferroelectrics;
3. the critical slowing down of the order parameter dynamics $\tau(\mathbf{q}_{\text{crit}}) \rightarrow \infty$ as $T \rightarrow T_c$ from above or below.

The breaking of the symmetry of the high temperature paraelectric phase is the result of the condensation of a polar soft phonon or a—usually overdamped—soft pseudospin wave mode, the frequency of which increases with decreasing temperature in the high-temperature phase and vanishes at T_c . The frozen out eigenvector of the soft mode represents the order parameter of the transition. In ferroelectrics the condensation of the soft mode occurs at the Brillouin zone center, whereas it occurs in antiferroelectrics at the Brillouin zone boundary.

The free energy of a ferroelectric with a one-component order parameter has a single minimum at $P = 0$ at $T > T_c$ and two minima at $+P$ and $-P$ below T_c corresponding to oppositely polarized domains [Figure 1(a)].

Solid solutions of ferroelectric (FE) and antiferroelectric (AFE) crystals form in the intermediate concentration range $x_{\text{FE}} \leq x \leq x_{\text{AFE}}$ (Figure 2) a pseudospin-like dipolar glassy phase where no macroscopic symmetry breaking takes place

Figure 1 Free energy surface in (a) a homogeneous ferroelectric and (b) a deuteron pseudospin glass

at any temperature and no long range order parameter appears. Instead we have a random local freeze-out of the dipoles and possibly an ergodic–nonergodic transition. The existence of the glassy phase is due to randomly competing ferroelectric and antiferroelectric interactions and the resulting random frustration of the system. The free energy surface of such a system is rough and fractal-like and exhibits a large number of nearly degenerate minima separated by high potential barriers² [Figure 1(b)]

In the concentration range $0 \leq x \leq x_{\text{FE}}$ and $x_{\text{AFE}} \leq x \leq 1$ (Figure 2) we have an inhomogeneous ferroelectric and antiferroelectric phase, respectively, where long range order and glassy order coexist at $T \neq 0$.

Figure 2 Phase diagram⁵ of the ferroelectric solid solution $\text{Rb}_{1-x}(\text{ND}_4)_x \text{D}_2\text{PO}_4$ which forms a deuteron glass in the intermediate concentration range $x_{\text{FE}} \leq x \leq x_{\text{AFE}}$. Also shown are the inhomogeneous ferroelectric and inhomogeneous antiferroelectric regions for $0 \leq x \leq x_{\text{FE}}$ and $x_{\text{AFE}} \leq x \leq 1$. The solid lines are calculated from the random bond–random field pseudospin Ising model. Also shown is the Almeida–Thouless (AT) line separating the ergodic from the nonergodic glassy phase

The local dipolar structure of the above phases can be characterized by a local polarization distribution function,³

$$W(p) = \frac{1}{N} \sum_i \delta(p - \langle S_i^z \rangle) \quad (4)$$

where the pseudospin $S_i^z = \pm 1$ describes the two orientational states of the dipole at site i , and the brackets $\langle \dots \rangle$ stand for the thermal average. In a homogeneous ferroelectric the first moment of $W(p)$,

$$P = \int W(p) p \, dp \neq 0 \quad T < T_c \quad (5a)$$

$$P = 0 \quad T > T_c \quad (5b)$$

is the spontaneous polarization

$$P = \frac{1}{N} \sum_i \langle S_i^z \rangle \quad (5c)$$

which is different from zero for $T < T_c$ and zero for $T > T_c$.

In a homogeneous ferroelectric

$$W(p) = \delta(p - P) \quad (5d)$$

and the second moment of $W(p)$ is zero,

$$\tilde{q} = q - P^2 = \int W(p) p^2 \, dp - P^2 = 0 \quad (5e)$$

In a proton or deuteron dipolar glass the first moment of $W(p)$ is zero as there is no long range order,

$$P = \int W(p) p \, dp = 0 \quad (6a)$$

but the second moment of $W(p)$ is different from zero,

$$q = \int W(p) p^2 \, dp \neq 0 \quad (6b)$$

Here, q is just the well known Edwards–Anderson glass order parameter which is also defined² as

$$q = \lim_{t \rightarrow \infty} \lim_{N \rightarrow \infty} \frac{1}{N} \sum_i \langle S_i^z(0) S_i^z(t) \rangle \quad (6c)$$

If there are no random fields present, we have a paraelectric–glass transition³ at T_g :

$$q = 0 \quad T > T_g \quad (7a)$$

$$q \neq 0 \quad T < T_g \quad (7b)$$

In the presence of a random field, which is conjugate to this glass order parameter, $q \neq 0$ at all temperatures.^{3,4} We have, however, at lower temperatures an ergodic–nonergodic transition below the Almeida–Thouless line in the random field variance–temperature plane where the pseudospin glass susceptibility, as well as the longest glass relaxation time,

diverge.^{2,5} Here the replica symmetry of the ‘ergodic’ glassy phase is broken² and instead of a single order parameter q we have an infinite number of order parameters represented by the order parameter function² $q(x)$.

In an inhomogeneous ferroelectric, on the other hand, both

$$P \neq 0 \quad (8a)$$

and

$$\tilde{q} = q - P^2 \neq 0 \quad (8b)$$

The local polarization distribution function $W(p)$ is reflected in the inhomogeneous NMR frequency spectrum $f(\omega)$ via

$$f(\omega) d\omega = W(p) dp \quad (9)$$

A knowledge of the inhomogeneous NMR frequency spectrum $f(\omega)$, obtainable by 2D ‘separation of interactions’ NMR, and the relationship $\omega = \omega(p)$ thus enables one to determine $W(p)$ and all its moments. This is of crucial importance in glasses and inhomogeneous ferroelectrics and antiferroelectrics.

3 NMR IN HOMOGENEOUS FERROELECTRICS AND ANTIFERROELECTRICS IN THE FAST MOTION REGIME

3.1 Deuteron NMR and Relaxation

In hydrogen-bonded ferroelectrics and antiferroelectrics the O–H···O bonds are of the double-well type (Figure 3) and are the main reversible dipoles in the structure. The two positions of the proton ($I = \frac{1}{2}$) or respectively deuteron ($I = 1$) in this limit can be represented by a pseudospin $S^z = \pm 1$. The quadrupole perturbed NMR frequency of the deuteron ω_i changes when the deuteron is transferred from the ‘left’ to the ‘right’ position, O–H···O $\leftrightarrow$ O···H–O, in the double-well potential:

$$\omega_i = \omega_0 + \omega_1 S_i^z(t) \quad (10a)$$

Figure 3 Double-well O–H···O hydrogen bond potential in hydrogen-bonded ferroelectrics. The two positions of the proton or deuteron in this potential can be described by a pseudospin $S^z = \pm 1$

Figure 4 Time dependence of the pseudospin variable $S^z(t)$ reflecting the deuteron motion between the two equilibrium sites in the O–H···O bond

In the ‘fast motion’ limit, where $\tau \ll \tau_{\text{NMR}} = 1/2\omega_1$ (Figure 4) the nucleus ‘sees’ just the time averaged value of $S_i^z(t)$ so that equation (10a) becomes

$$\omega_i = \omega_0 + \omega_1 p_i \quad (10b)$$

where $p_i = \langle S_i^z(t) \rangle$ is the local polarization. In a homogeneous ferroelectric, where equation (5d) holds, $p_i = p_j = p = P$, so that ^2H NMR provides a method for a microscopic measurement of the long range order parameter P as well as yielding direct information about the deuteron order–disorder transition at T_c in KD_2PO_4 -type crystals.¹ As it can be seen from Figure 5, $\langle S^z(t) \rangle = 0$ above T_c and $\langle S^z(t) \rangle \neq 0$ below T_c . The deuterons are dynamically disordered between the two equilibrium sites above T_c and order into one of the two positions below T_c .⁶ The T dependence of $p = P$ is equal to the one determined by macroscopic polarization measurements.

The fluctuating part of the local polarization $p_i = p + \delta p_i(t)$ and the related part of the quadrupole coupling Hamiltonian $\hat{\mathcal{H}}_Q^{(1)}(t)$,

$$\hat{\mathcal{H}}_Q(t) = \langle \hat{\mathcal{H}}_Q \rangle + \hat{\mathcal{H}}_Q^{(1)}(t) \quad (11a)$$

produces, in agreement with equations (2) and (3), a characteristic dip in T_1 at T_c (Figure 6). The form of the T_1^{-1} anomaly

Figure 5 Temperature dependence of the quadrupole splitting of the deuteron NMR lines in CsD_2AsO_4

Figure 6 Temperature dependence of the deuteron spin-lattice relaxation rate in KD_2PO_4 at $B_0 = 1.65 \text{ T}$

is the one expected¹ for the condensation of an overdamped soft pseudospin wave mode:

$$T_1^{-1} \propto \ln \frac{T - T_c}{T_c} + \text{constant} \quad T > T_c \quad (11b)$$

$$T_1^{-1} \propto 1 - p^2 \quad T < T_c \quad (11c)$$

From the above data the noninteracting deuteron correlation time, i.e. the time the deuteron stays at a given site before it jumps to the other site in the $\text{O}-\text{D}\cdots\text{O}$ potential, is determined as $\tau_0 = 2.7 \times 10^{-13} \text{ s}$ at room temperature. This justifies the fast motion approximation. Similar results were obtained in other hydrogen bonded ferroelectrics.^{1,7}

3.2 Oxygen-17-Proton Nuclear Quadrupole Double Resonance

In view of the ‘geometrical’ isotope effect⁸ and the resulting expansion and changes in the shape of the hydrogen bond potential on deuteration one cannot simply transfer the conclusions obtained for deuterated crystals to the undeuterated ones. Since the distance between the two equilibrium sites of the hydrogen in short $\text{O}-\text{H}\cdots\text{O}$ bonds ($R_{\text{O}-\text{O}} \leq 2.49 \text{ \AA}$) may be $0.35 \text{ \AA}$ or less, it is difficult to determine by neutron diffraction whether the proton is located in the center of the hydrogen bond or dynamically disordered between two separate, off-center equilibrium sites. For $T > T_c$ a single peaked proton density distribution in the center of the hydrogen bond is usually observed by neutron scattering. Below T_c the diffraction data show an off-center position of the proton.

The answer is provided by $^{17}\text{O}-^1\text{H}$ quadrupole double resonance spectroscopy and the direct determination of the $^{17}\text{O}-^1\text{H}$ distance from the magnetic dipole-dipole fine structure of the ^{17}O NQR lines.⁹

As an example let us consider⁷ RbH_2PO_4 , which is isomorphous with KH_2PO_4 and has all $\text{O}-\text{H}\cdots\text{O}$ bonds equivalent. In this system the PO_4 groups are linked by $\text{O}-\text{H}\cdots\text{O}$ bonds. In view of the low natural abundance of ^{17}O (0.037%) there is at most one ^{17}O nucleus ($I = \frac{5}{2}$) per $\text{O}-\text{H}\cdots\text{O}$ bond.

The energies of the three doubly degenerate ($|\pm \frac{1}{2}\rangle, |\pm \frac{3}{2}\rangle, |\pm \frac{5}{2}\rangle$) ^{17}O quadrupole energy levels $E = x A$, $A = e^2 q Q / 4I(2I - 1)$, $eq = V_{zz}$ can be obtained from

$$x^3 - 7(3 + \eta^2)x - 20(1 - \eta^2) = 0 \quad (12)$$

where $\eta = (V_{xx} - V_{yy})/V_{zz}$ is the asymmetry parameter of the EFG tensor and where $V_{zz} \geq V_{yy} \geq V_{xx}$. For small η we have

$$\nu_{1/2 \rightarrow 3/2} = \frac{3e^2 q Q}{20h} \left(1 + \frac{59}{54} \eta^2 \right) \quad (13a)$$

$$\nu_{1/2 \rightarrow 5/2} = \frac{3e^2 q Q}{10h} \left(1 - \frac{11}{54} \eta^2 \right) \quad (13b)$$

and $\nu_{1/2 \rightarrow 5/2} = \nu_{1/2 \rightarrow 3/2} + \nu_{3/2 \rightarrow 5/2}$.

If the proton is centrally located we expect just one set of ^{17}O NQR lines ($\nu_{1/2 \rightarrow 3/2}, \nu_{3/2 \rightarrow 5/2}, \nu_{1/2 \rightarrow 5/2}$) per $^{17}\text{O}-\text{H}\cdots\text{O}$ bond. If the proton is located in an ‘off-center’ site we expect, in view of the random occurrence of the ^{17}O isotope, two sets of ^{17}O NQR lines per $\text{O}-\text{H}\cdots\text{O}$ bond. One of them would correspond to the proton in the ‘close’ position, i.e. $^{17}\text{O}-\text{H}\cdots\text{O}$, and the other to the proton in the ‘far’ position, i.e. $^{17}\text{O}\cdots\text{H}-\text{O}$. If the protons are dynamically disordered between the two ‘off’-center sites, the observed ^{17}O EFG tensor should be an average of the tensors for the two separate ‘off’-center sites, the ‘far’ and the ‘close’ one. It should be noted that the ^{17}O quadrupole coupling constant increases with decreasing $\text{O}-\text{H}$ bond distance,⁸ thus allowing for a discrimination between ‘close’ and ‘far’ sites.

The ^{17}O nuclear quadrupole double resonance results for RbH_2PO_4 are shown in Figure 7. Above T_c only three ^{17}O lines ($\nu_{1/2 \rightarrow 3/2}, \nu_{3/2 \rightarrow 5/2}, \nu_{1/2 \rightarrow 5/2}$) are observed, demonstrating that all PO_4 oxygen sites are equivalent on the NQR timescale. Below T_c each line splits symmetrically into two components, demonstrating that we are dealing with dynamic disorder between two equivalent sites above T_c . The average value of the two components is constant while the difference is proportional to the order parameter p and measures the time averaged asymmetry in the hydrogen bond potential below T_c . We thus have

$$\begin{aligned} \langle \mathbf{V} (^{17}\text{O}-\text{H}) \rangle &= \langle \mathbf{V} (^{17}\text{O}\cdots\text{H}) \rangle \\ &= \frac{1}{2} [\mathbf{V} (^{17}\text{O}-\text{H}) \\ &\quad + \mathbf{V} (^{17}\text{O}\cdots\text{H})] \quad T > T_c \end{aligned} \quad (14a)$$

Figure 7 Temperature dependence of (a) the ^{17}O NQR transition frequencies in RbH_2PO_4 and (b) the quadrupole coupling constant and asymmetry parameter

and

$$\langle \mathbf{V} (^{17}\text{O}-\text{H}) \rangle = \frac{1+p}{2} \mathbf{V} (^{17}\text{O}-\text{H}) + \frac{1-p}{2} \mathbf{V} (^{17}\text{O} \cdots \text{H}) \quad T < T_c \quad (14b)$$

$$\langle \mathbf{V} (^{17}\text{O} \cdots \text{H}) \rangle = \frac{1-p}{2} \mathbf{V} (^{17}\text{O}-\text{H}) + \frac{1+p}{2} \mathbf{V} (^{17}\text{O} \cdots \text{H}) \quad T < T_c \quad (14c)$$

Figure 8 Field sequence for the ^{17}O -H double resonance in the laboratory frame experiment

The difference

$$\langle \mathbf{V} (^{17}\text{O}-\text{H}) \rangle - \langle \mathbf{V} (^{17}\text{O} \cdots \text{H}) \rangle = p[\mathbf{V} (^{17}\text{O}-\text{H}) \times - \mathbf{V} (^{17}\text{O} \cdots \text{H})] \quad (14d)$$

is here indeed proportional to p and allows for a measurement of the local asymmetry of the hydrogen bond potential in frequency units.

The corresponding measuring sequence for the ^{17}O - ^1H double resonance experiment in the laboratory frame is schematically shown in Figure 8.

An independent confirmation of the above results is provided by the proton magnetic dipolar fine structure of the ^{17}O lines obtained with a double frequency irradiation technique.⁹ For $\eta = 0$, $E_{\pm 5/2}$ and $E_{\pm 3/2}$ split up into two doubly degenerate energy levels,

$$E_{\pm 5/2} = \frac{e^2qQ}{4} \pm \frac{5}{2}K\sqrt{1+3\cos^2\theta} \quad (15a)$$

$$E_{\pm 3/2} = -\frac{e^2qQ}{20} \pm \frac{3}{2}K\sqrt{1+3\cos^2\theta} \quad (15b)$$

whereas $E_{\pm 1/2}$ splits into four levels,

$$E_{\pm 1/2} = -\frac{e^2qQ}{5} + \frac{K}{2}[3 \pm \sqrt{37-12\cos 2\theta}] \quad (15c)$$

$$E_{\pm 1/2} = -\frac{e^2qQ}{5} + \frac{K}{2}[-3 \pm \sqrt{13-12\cos 2\theta}] \quad (15d)$$

Here $K/\hbar = 8.16 \text{ kHz}/R_{\text{O-H}}^3$ (angstroms), $\hbar$ is Planck's constant, and θ is the angle between the largest principal axis of the axially symmetric ($\eta = 0$) ^{17}O EFG tensor and the ^{17}O -H bond direction.

The effective dipolar splitting of the ^{17}O NQR lines is determined by

$$\langle R^{-3} \rangle = \frac{1+p}{2} R_{\text{O-H}}^{-3} + \frac{1-p}{2} R_{\text{O} \cdots \text{H}}^{-3} \quad T < T_c \quad (16a)$$

where p can be determined from the temperature dependence of the ^{17}O lines. The ^{17}O -H distance for the 'close' proton

site is here obtained as $R_{O-H} = 1.06 \pm 0.01 \text{ \AA}$ at $T = 138 \text{ K}$, i.e. well below T_c . The result agrees with the one obtained by neutron scattering.

Above T_c the proton spends an equal amount of time at the ‘close’ ($R_{O-H} = 1.06 \text{ \AA}$) and ‘far’ ($R_{O\cdots H} = 1.45 \text{ \AA}$) equilibrium site so that the dipolar splitting is characterized by an ‘apparent’ $^{17}\text{O-H}$ distance

$$\langle R^{-3} \rangle = \frac{1}{2} [R_{O-H}^{-3} + R_{O\cdots H}^{-3}] \quad T > T_c \quad (16b)$$

yielding $R = 1.18 \text{ \AA}$. If, on the other hand, the proton is above T_c , situated in the center of the O–H–O bond, the effective O–H distance obtained from the dipolar fine structure would be

$$R_{\text{symm}}(\text{O-H}) = 1.225 \text{ \AA} \quad T > T_c \quad (16c)$$

which would contradict the experimental data. The ^{17}O quadrupole coupling as well as the $^{17}\text{O-H}$ magnetic dipolar fine structure thus provide direct evidence for the proton intra- $^{17}\text{O-H} \cdots \text{O} \leftrightarrow ^{17}\text{O} \cdots \text{H-O}$ motion between the two sites and the dynamic order–disorder nature of the phase transition in RbH_2PO_4 .

Similar results were obtained for KH_2PO_4 , CsH_2PO_4 , TiH_2PO_4 , PbHPO_4 , as well as squaric acid ($\text{C}_4\text{H}_2\text{O}_2$) and $\text{KH}_3(\text{SeO}_3)_2$.^{7,10} In partially deuterated $\text{RbH}_{2x}\text{D}_{2(1-x)}\text{PO}_4$ the results show that the O–H $\cdots$ O bonds are practically identical to the ones in pure RbH_2PO_4 whereas the O–D $\cdots$ O bonds expand and show a nearly 25% higher spontaneous asymmetry below T_c than the O–H $\cdots$ O bonds.⁷

3.3 Proton Chemical Shift Tensors

For protons ($I = \frac{1}{2}$) in solids, the chemical shift term $\hat{\mathcal{H}}_\sigma$ in the spin Hamiltonian

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_D + \hat{\mathcal{H}}_\sigma \quad (17a)$$

$$\hat{\mathcal{H}}_\sigma = \gamma \sum_i \hat{\mathbf{I}}_i \cdot \boldsymbol{\sigma}_i \cdot \mathbf{B}_0 \quad (17b)$$

is usually much smaller than the dipolar term so that proton chemical shifts are lost in the dipolar width of the NMR line. Using high-resolution NMR-in-solids techniques like the WAHUA sequence,¹¹

$$(\tau, P_x, 2\tau, P_{-x}, \tau, P_y, 2\tau, P_{-y})$$

the homonuclear dipolar broadening can be eliminated while the chemical shifts are reduced by $\sqrt{3}$. This allows for a determination of the proton chemical shift tensors $\boldsymbol{\sigma}$ from the angular dependence of the spectra. Such measurements were performed in KH_2PO_4 and other hydrogen bonded systems.¹² The information obtained is in principle similar to that obtained from the deuteron quadrupole coupling data but the experiments are more tedious and the resolution is lower.

3.4 Phosphorus-31 Chemical Shift Tensors

Whereas ^{17}O NQR and deuteron quadrupole perturbed NMR measure the single-particle intra-hydrogen bond dynamics, the ^{31}P chemical shift tensor $\boldsymbol{\sigma}$ interaction in KH_2PO_4 -type crystals measures the local arrangement of the four O–H $\cdots$ O bonded protons in the hydrogen bonds linking a given PO_4 group to its neighbors. The chemical shift term is

$$\hat{\mathcal{H}}_\sigma = \gamma \sum_i \hat{\mathbf{I}}_i \cdot \boldsymbol{\sigma}_i \cdot \mathbf{B}_0 \quad (18a)$$

where

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}(p_1, p_2, p_3, p_4) \quad (18b)$$

The temperature dependence of the ^{31}P chemical shift on going through T_c in KD_2PO_4 is shown^{7,10} in Figure 9(a). There are four ^{31}P nuclei per unit cell of KH_2PO_4 both above and below T_c . The edges of two PO_4 tetrahedra are rotated by $+13^\circ$ with respect to the orthorhombic a, b axes (A sites) whereas the other two are rotated by -13° (B sites). Above T_c all ^{31}P sites in the unit cell are chemically and physically equivalent due to dynamic proton disorder in the O–H $\cdots$ O bonds. The ^{31}P chemical shift tensor is axially symmetric around the fourfold c axis which passes through

Figure 9 (a) Temperature dependence of the ^{31}P chemical shift on cooling through T_c in KD_2PO_4 . (b) Splitting of the ^{31}P NMR line¹¹ in pseudo-1D CsD_2PO_4 where the O–H(1) $\cdots$ O bonds are ordered above and below T_c whereas the O–H(2) $\cdots$ O bonds are disordered above T_c and ordered below T_c and where $\sigma_{T>T_c} = \frac{1}{2}(\sigma_1 + \sigma_2)$ and $\sigma_{T<T_c} = \frac{1}{2}(\sigma_1 - \sigma_2)$.

the phosphorus sites. Below T_c there are four physically nonequivalent ^{31}P sites, which are all chemically equivalent and which reflect the ordering of the four protons into two ‘close’ and two ‘far’ sites in the $\text{O}-\text{H}\cdots\text{O}$ bonds: $\sigma_1 = \sigma_A(+\mathbf{P})$, $\sigma_2 = \sigma_A(-\mathbf{P})$, $\sigma_3 = \sigma_B(+\mathbf{P})$, $\sigma_4 = \sigma_B(-\mathbf{P})$. The paraelectric σ tensor is the average of the four ferroelectric ones.^{7,10} This confirms that the phase transition in KH_2PO_4 is a protonic order–disorder one and is not driven by electronic instabilities.

The largest principal axes of the ^{31}P chemical shift tensor is nearly exactly parallel to the line connecting the two PO_4 oxygens to which the protons are directly attached. A change in the H_2PO_4 proton ‘arrangement’ from the ‘top’ to the ‘bottom’ oxygens, as viewed along the c axis, results in a polarization reversal ($\mathbf{P} \rightarrow -\mathbf{P}$) and in a rotation of the two largest principal axes of the ^{31}P σ tensor by 90° . The ^{31}P σ tensor is thus a very sensitive indicator of the arrangement of the four protons around a given PO_4 group in KH_2PO_4 crystals.

Similar results were also obtained in pseudo-1D CsD_2PO_4 ¹³ [Figure 9(b)] and PbHPO_4 ¹⁴ using high-resolution NMR-in-solids techniques.

3.5 Arsenic-75 Quadrupolar Coupling

Information similar to that from the ^{31}P chemical shift tensor can be obtained from the ^{75}As quadrupole coupling tensor in KH_2AsO_4 -type arsenates.

Here, however, the resolution of the experiment is much larger as the ^{75}As NQR frequency changes¹⁰ from ≈ 3.5 MHz at $T > T_c$ to ≈ 35 MHz at $T < T_c$ (Figure 10). The ^{75}As EFG tensor as well depends on the arrangement of the four protons around a given AsO_4 group:

$$\mathbf{V} = \mathbf{V}(p_1, p_2, p_3, p_4) \quad (19)$$

The direction of the largest principal axis (V_{zz}) of this tensor is parallel to the line connecting the two oxygens in the AsO_4 group to which the two protons are directly attached, whereas the smallest principal axis (V_{xx}) is parallel to the direction of the electric dipole moment of the H_2AsO_4 group.

The ^{75}As EFG tensors determined^{1,7,10,15} in ferroelectric KH_2AsO_4 and antiferroelectric $\text{NH}_4\text{H}_2\text{AsO}_4$ could be thus assigned to the six Slater¹⁶ H_2AsO_4 configurations predicted by the Slater–Nagamiya model¹⁶ of the phase transition in KH_2PO_4 . In ferroelectric KH_2AsO_4 both ‘close’ hydrogens are either attached to the ‘upper’ ($\mathbf{V}^{(1)}$) or to the ‘lower’ two H_2AsO_4 oxygens ($\mathbf{V}^{(2)}$) as viewed along the c axis,

so that the dipole moment points along $\pm c$. In antiferroelectric $\text{NH}_4\text{H}_2\text{AsO}_4$ on the other hand, one hydrogen is attached to the ‘upper’ and one to the ‘lower’ oxygen,

resulting in four ‘antiferroelectric’ H_2AsO_4 arrangements—($\mathbf{V}^{(3)}$, $\mathbf{V}^{(4)}$, $\mathbf{V}^{(5)}$, $\mathbf{V}^{(6)}$)—with dipole moments along the $\pm b$

Figure 10 (a) Temperature dependence of the ^{75}As NQR frequency ν_Q in KH_2AsO_4 on cooling through T_c . (b) Dependence of the inverse ^{75}As quadrupole coupling constant $(e^2qQ/h)^{-1}$ on $(T - T_c)/T_c$ in KH_2AsO_4 -type crystals above T_c

and $\pm a$ crystal axes. In the antiferroelectric domain, where the sublattice polarization $\vec{\mathbf{P}} \parallel [100]$ is along the $\pm a$ axis, one sublattice corresponds to $\mathbf{V}^{(3)}$ and the other to $\mathbf{V}^{(4)}$, whereas for $\vec{\mathbf{P}} \parallel [010]$ the corresponding EFG tensors are $\mathbf{V}^{(5)}$ and $\mathbf{V}^{(6)}$. These results represented the first direct proof that the antiferroelectric proton ordering suggested by Nagamiya¹⁶ is correct.

In the paraelectric phase each H_2AsO_4 group fluctuates between the six Slater configurations. The fluctuations result in a time averaging of the EFG tensors and in an anomalous increase in the ^{75}As spin–lattice relaxation rate as $T \rightarrow T_c$ ¹⁹ (Figure 11). The ^{75}As T_1^{-1} has been measured by the proton–arsenic cross-relaxation technique in the dipolar frame.¹⁷

3.6 Fluctuations at Cationic Sites

In contrast to the nuclei discussed so far which were all covalently bonded, the EFG tensor at the K, Cs or Rb sites in

Figure 11 Temperature dependence of the arsenic spin-lattice relaxation rate in the dipolar (rotating) frame as determined by proton-arsenic cross relaxation

KH₂PO₄-type ferroelectrics is of ionic character. These nuclei are thus nonlocal probes which measure the charge distribution and order on a scale of 40–50 unit cells (i.e. more than 10² O–H···O bonds). Here

$$\mathbf{V}_i = \mathbf{V}_i(p_1, p_2, \dots, p_L) \quad (20a)$$

The temperature dependence of the ¹³³Cs ($I = \frac{7}{2}$) quadrupole coupling constant in CsH₂AsO₄, for instance⁷ can be described above T_c by

$$\langle \mathbf{V}_i \rangle = \mathbf{V}_0 \quad T > T_c \quad (20b)$$

if the mean square fluctuations in the order parameter can be neglected. Below T_c , on the other hand, one finds

$$\langle \mathbf{V}_i \rangle = \mathbf{V}_0 + \mathbf{A}p + \mathbf{B}p^2 \quad T < T_c \quad (20c)$$

where the forms of the $\mathbf{V}_0$, $\mathbf{A}$, and $\mathbf{B}$ tensors are determined by crystal symmetry.^{7,18} Similar results are obtained for the ³⁹K and ⁸⁷Rb quadrupole coupling tensors in other KH₂PO₄-type crystals.¹

3.7 NMR in Perovskite Ferroelectrics

The local properties of phase transitions in perovskite-type ferroelectrics and antiferroelectrics have been extensively studied by NMR.²¹ Cotts and Knight²¹ and Hewitt²¹ were the first to study electric quadrupole interactions in perovskites.

Hewitt²¹ in particular measured the temperature dependence of the EFG tensor at the ⁹³Nb sites in KNbO₃. The spin-lattice relaxation studies of NaNbO₃²¹ gave important information on the softening of the collective rotations of the oxygen tetrahedra at the M point, $\mathbf{q} = (\frac{1}{2}, \frac{1}{2}, 0)$ —of the Brillouin zone.

4 NMR IN THE SLOW AND INTERMEDIATE MOTION REGIME

4.1 Dynamic Symmetry Breaking and NMR in KSCN, RbSCN, and NH₄SCN Antiferroelectrics

The second-order quadrupole shifts¹⁹ of the ³⁹K or ⁸⁷Rb $\frac{1}{2} \rightarrow -\frac{1}{2}$ NMR transitions in tetragonal KSCN and RbSCN show the effects of dynamic symmetry breaking on the NMR timescale.^{19,20} The symmetry of the angular rotation pattern in the high-temperature paraelectric tetragonal phase is lower than the K or Rb site symmetry as determined by X-ray scattering¹⁹ [Figure 12(a) and (b)]. At the same time the ³⁹K and ⁸⁷Rb ‘site’ and ‘90° domain’ doublet splittings which are proportional to the long range order parameter vanish above T_c [Figure 12(c)] as expected from equations (1a) and (1b).

The above systems undergo at T_c antiferroelectric–paraelectric phase transitions connected with a head–tail ordering of the SCN[−] groups. These groups are dynamically disordered above T_c and order in an antiparallel arrangement below T_c , resulting in a doubling of the unit cell size and the formation of 0, 90, 180, and 270° orthorhombic domains. The shift of the K⁺ or Rb⁺ ions from their position on the fourfold rotation axis is linearly coupled to the orientational degrees of freedom of the SCN[−] ions.

The NMR results¹⁹ show that for the second-order shifts and corresponding lineshapes the time fluctuating quadrupolar perturbation $\hat{\mathcal{H}}_Q^{(1)}(t)$, connected with the flipping of the SCN[−] groups, averages out in two steps.²⁰ This is because both diagonal and off-diagonal matrix elements—in the representation of eigenstates of the main Hamiltonian—are important. A resonance line is a doublet with a splitting $4A$ at very long correlation times ($A\tau \gg 1$) where the spectrum is the same as in the case of two static Hamiltonians

$$\hat{\mathcal{H}}_A = \hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q^{(0)} \rangle + \hat{\mathcal{H}}_Q^{(1)} \quad (21a)$$

and

$$\hat{\mathcal{H}}_B = \hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q^{(0)} \rangle - \hat{\mathcal{H}}_Q^{(1)} \quad (21b)$$

It becomes a singlet when τ^{-1} exceeds the doublet splitting, i.e. when $A\tau \ll 1$. The second-order shift of the resonance line caused by the off-diagonal matrix element of the quadrupolar perturbation $\hat{\mathcal{H}}_Q^{(1)}(t)$ vanishes, however, only when τ^{-1} exceeds the resonance frequencies ω_L of the main Hamiltonian, $\hat{\mathcal{H}}_Z + \langle \hat{\mathcal{H}}_Q^{(0)} \rangle$. For $A\tau \ll 1$, $\omega_L\tau \gg 1$ we are thus in the intermediate motion limit and have a partial motional averaging. The doublet splitting induced by $\hat{\mathcal{H}}_Q^{(1)}(t)$ is averaged

Figure 12 (a) Temperature dependence of the ^{39}K angular rotation pattern in KSCN for the c rotation above T_c and (b) below T_c . The domain splitting seen below T_c [inset to (b)] disappears above T_c whereas the angular dependence observed above T_c is incompatible with the tetragonal symmetry of the phase. (c) Temperature dependence of domain splitting

out, but the second-order quadrupolar shift induced by $\hat{\mathcal{H}}_Q^{(1)}(t)$ is still nonzero:

$$\Delta\omega_{1/2 \rightarrow -1/2}(\tau) = \Delta\omega_{1/2 \rightarrow -1/2}^{(0)} + \Delta\omega_{1/2 \rightarrow -1/2}^{(1)}(\tau) \quad (22a)$$

where

$$\Delta\omega_{1/2 \rightarrow -1/2}^{(1)}(\tau) \propto \frac{(\omega_L \tau)^2}{1 + (\omega_L \tau)^2} \quad (22b)$$

It is only in the fast motion limit, $\omega_L \tau \ll 1$, that $\Delta\omega_{1/2 \rightarrow -1/2}^{(1)}(\tau) \rightarrow 0$ and the angular dependence of the second-order quadrupolar shift is $\Delta\omega_{1/2 \rightarrow -1/2}^{(0)}$, i.e. it is determined by the time averaged Hamiltonian $\langle \hat{\mathcal{H}}_Q^{(0)} \rangle$.

In agreement with this model and equations (2a)–(3c), the ^{39}K and ^{87}Rb spin–lattice relaxation rates show no anomaly at T_c as all critical factors in equation (2b) cancel (Figure 13). T_1 is proportional to $\omega_L^2 \tau_0$, and continues to decrease with increasing temperature as the crystal is heated above T_c since τ_0 is thermally activated.

The dynamic symmetry breaking effects are not seen in the ^{14}N ($I = 1$) NMR in NH_4SCN ,¹⁹ as here first-order quadrupole splittings were studied where off-diagonal matrix elements are not important.

4.2 Dynamic Symmetry Breaking in KH_2AsO_4

In addition to the broad paraelectric arsenic lines, sharp ‘ferroelectric’ arsenic $\frac{1}{2} \rightarrow -\frac{1}{2}$ lines have been observed in KH_2AsO_4 well above T_c .¹⁵ The angular dependence of these lines shows that here the symmetry of the paraelectric phase is also broken on the timescale of the NMR Larmor frequency. In contrast to KSCN and RbSCN where—in view of the large moment of inertia of the SCN group and the correlations between the flips of different SCN^- groups induced by the small available space for single ion reorientations—the intrinsic dynamics are very slow, we have in KH_2AsO_4 a high frequency soft mode similarly as in KH_2PO_4 . The formation of nearly static polar clusters above T_c and the resulting dynamic symmetry breaking may thus be, in contrast to KSCN and RbSCN, induced here by defects.

Figure 13 Temperature dependence of the normalized ^{87}Rb NMR T_1 components in RbSCN

5 NMR IN PROTON AND DEUTERON GLASSES

5.1 Determination of the Edwards–Anderson Order

Parameter q_{EA} in the Fast Motion Limit

Solid solutions $\text{Rb}_{1-x}(\text{ND}_4)_x\text{D}_2\text{PO}_4$ (RADP) of ferroelectric RbH_2PO_4 and antiferroelectric $\text{ND}_4\text{D}_2\text{PO}_4$ represent a randomly frustrated hydrogen-bonded system with competing ferroelectric and antiferroelectric interactions. For $0.22 \leq x \leq 0.78$ the system forms a deuteron glass²¹ with no macroscopic symmetry breaking and no spontaneous polarization at any temperature. Here too the O–D···O bond represents a two-position reorientable dipole (see Figure 3) which can be described by an Ising pseudospin, $S^z = \pm 1$. In contrast to magnetic spin glasses where we deal with random bond interactions, proton and deuteron glasses are characterized by the presence of both random bonds and random fields²²

$$\hat{\mathcal{H}} = - \sum_{i < j} J_{ij} S_i^z S_j^z - \sum_i f_i S_i^z \quad (23)$$

Here the J_{ij} are quenched random interactions and f_i are quenched random fields characterized by their second cumulants $[J_{ij}^2]_{\text{AV}} = J^2/N$ and $[f_i f_j]_{\text{AV}} = \delta_{ij} \Delta$. The random bond distribution is assumed to be Gaussian and centered around a mean value $J_0 = J_{\text{AFEX}} + J_{\text{FE}}(1-x)$ where x represents the NH_4 concentration. J^2 and Δ , on the other hand, are proportional to $x(1-x)$ and vanish for $x \rightarrow 0$ and $x \rightarrow 1$. For $|J_0| < J$ the system forms a glass phase without long range order whereas for $|J_0| > J$ a long range ordered inhomogeneous ferroelectric or antiferroelectric phase is predicted to occur.

The basic question in deuteron glasses is how to measure the Edwards–Anderson order parameter²

$$q_{\text{EA}} = \frac{1}{N} \sum_i \langle S_i^z \rangle^2 \quad (24)$$

as there is no macroscopic conjugate field attached to it. The answer is provided by NMR. In the fast motion limit NMR also allows for a direct determination of the local polarization distribution function $W(p)$, the second moment of which is q_{EA} .

In the simplest case the local NMR frequency ω_i of the deuteron in an O–D···O bond is in the fast motion limit [$\omega_{\text{AB}} \tau \ll 1$, $\omega_{\text{AB}} = \omega_{\text{A}} - \omega_{\text{B}}$] linearly related to the pseudospin polarization $\langle S_i^z \rangle = p_i$ of this bond:

$$\omega_i = \omega_0 + \omega_1 \langle S_i^z \rangle = \omega_0 + \omega_1 p_i \quad (25)$$

O–D···O bonds with different local polarizations p_i will thus have different NMR frequencies resulting in an inhomogeneous broadening of the NMR line. The resulting frequency distribution,

$$f(\omega) = \frac{1}{N} \sum_i \delta(\omega - \omega_i) = [\delta(\omega - \omega_i)]_{\text{AV}} \quad (26)$$

is related to the local polarization distribution $W(p)$ [equation (4)] via

$$f(\omega) d\omega = W(p) dp \quad (27)$$

A measurement of $f(\omega)$ thus allows for a determination of $W(p)$ and its second moment q_{EA} if the relation between ω_i and p_i [equation (25)] is known from experiments on pure systems. q_{EA} in particular is obtained from

$$M_2[f(\omega)] = \int d\omega f(\omega) (\omega - \omega_0)^2 = \omega_1^2 q_{\text{EA}} \quad (28)$$

Such experiments have been indeed performed,⁴ and the results can be well described by the random bond–random field model.^{4,22} The temperature dependence of q_{EA} (Figure 14) in particular demonstrates that in contrast to magnetic spin glass, random fields are present in addition to random bonds. From the shape of the deuteron NMR spectrum [Figure 15(a)] the temperature dependence of $W(p)$ can be determined [Figure 15(b)]. $W(p)$ is here symmetric around $p = 0$ and changes from a single-peaked to double-peaked form with decreasing temperature.

At lower temperatures where the pseudospin fluctuations are no longer very fast as compared to the rigid lattice quadrupole splittings ω_{AB} , we have to take into account the additional broadening due to the slowing down of the fluctuations by convoluting $W(p)$ with the well known dynamic lineshape $I(\omega, p, \tau)$ for exchange in an asymmetric two-site potential. Equation (26) now becomes

$$f(\omega) = \int I(\omega, p, \tau) W(p) dp \quad (29)$$

When the fluctuations become too slow, $\omega_{\text{AB}} \tau \geq 1$, the second moment of the lineshape is no longer proportional to q_{EA} but

Figure 14 Temperature dependence of q_{EA} as determined from the second moment of the $^{87}\text{Rb } \frac{1}{2} \rightarrow -\frac{1}{2}$ NMR spectra in $\text{Rb}_{0.56}(\text{ND}_4)_{0.44}\text{D}_2\text{PO}_4$. The dotted line represents the fit to the random bond–random field model with $\Delta/J^2 = 0.35$, $T_g = J/k = 90$ K, whereas the dashed line represents the best fit for the pure random field model where $T_g = 0$ K and $\sqrt{\Delta}/k = 68.2$ K. The solid line represents the fit to the pure random bond model with $T_g = 151$ K and $\sqrt{\Delta}/k = 0$ K

Figure 15 (a) O–D···O deuteron NMR spectrum in $\text{Rb}_{0.56}(\text{ND}_4)_{0.44}\text{D}_2\text{PO}_4$ at various temperatures. (b) Temperature dependence of the local polarization distribution function $W(p)$ for $\text{Rb}_{0.56}(\text{ND}_4)_{0.44}\text{D}_2\text{PO}_4$ where $\Delta/J^2 = 0.35$

approaches a constant value determined by $I(\omega, p, \tau = \infty)$. Here 1D NMR cannot be used for a determination of q .

5.2 Determination of the Glass Order Parameter q in the Slow Motion Limit

In the slow motion limit where $\omega_{AB}\tau \gg 1$ the nucleus ‘sees’ the instantaneous value of the Hamiltonian corresponding to $S^z = \pm 1$. The NMR spectrum of the O–D···O bond deuteron will thus consist of two lines,

$$\omega_A = \omega_0 + \omega_1 \quad (30a)$$

and

$$\omega_B = \omega_0 - \omega_1 \quad (30b)$$

corresponding to the ‘left’ and ‘right’ position of the deuterons in the double-minimum hydrogen bond potentials. 2D ‘exchange’ NMR spectroscopy²³ can be used here to determine the glass order parameter q as well as the intrabond deuteron jump rate. The corresponding pulse sequence

Figure 16 2D exchange NMR pulse sequence²⁴

(Figure 16) developed by Spiess et al.²⁴ selects the signal of the form

$$\begin{aligned} F(t_1, t_2, t_m) = & \exp(-t_m/T_1) \exp[-(t_1 + t_2)/T_2] \\ & \times [a_{AA}(t_m) \cos(\omega_A t_1) \cos(\omega_A t_2) \\ & + a_{BB}(t_m) \cos(\omega_B t_1) \cos(\omega_B t_2) \\ & + a_{AB}(t_m) \cos(\omega_A t_1) \cos(\omega_B t_2) \\ & + a_{BA}(t_m) \cos(\omega_B t_1) \cos(\omega_A t_2)] \quad (31) \end{aligned}$$

After a Fourier transformation with respect to t_1 and t_2 the results are presented in the $\omega_1 - \omega_2$ plane. If no intrabond deuteron exchange, $A \leftrightarrow B$, has taken place the absorption peaks lie on the diagonal of the $\omega_1 - \omega_2$ plane at (ω_A, ω_A) and (ω_B, ω_B) . If intrabond deuteron transfer has taken place between the two physically nonequivalent sites A and B, we also find cross peaks at (ω_A, ω_B) and (ω_B, ω_A) . The intensities of the cross peaks (Figure 17) are proportional to the fraction of nuclei that have undergone exchange in the time t_m . Since

$$a_{AA}(\infty) = \frac{1}{N} \sum_i W_{Ai}^2 \quad (32a)$$

$$a_{BB}(\infty) = \frac{1}{N} \sum_i W_{Bi}^2 \quad (32b)$$

and

$$a_{AB}(\infty) = a_{BA}(\infty) = \frac{1}{N} \sum_i W_{Ai} W_{Bi} \quad (32c)$$

where W_{Ai} is the probability of finding the deuteron of the i th O–D···O bond in site A, etc., we get for the ratio of the intensities of the cross peaks to the diagonal peaks in the limit $t_m \rightarrow \infty$ the expression

$$R(t_m \rightarrow \infty) = \frac{a_{AB}(\infty)}{a_{AA}(\infty)} = \frac{\sum_i W_{Ai} W_{Bi}}{\sum_i W_{Ai}^2} \quad (33a)$$

Using $\langle S_i^z \rangle = W_{Ai} - W_{Bi}$ and

$$q = \frac{1}{N} \sum_i \langle S_i^z \rangle^2 = \frac{1}{N} \sum_i (W_{Ai} - W_{Bi})^2 \quad (33b)$$

as well as

$$\frac{1}{N} \sum_i (W_{Ai} + W_{Bi})^2 = 1 \quad (33c)$$

Figure 17 2D O–D...O intrabond deuteron ‘exchange’ NMR spectra of $\text{Rb}_{0.68}(\text{ND}_4)_{0.32}\text{D}_2\text{AsO}_4$ for $\mathbf{a} \perp \mathbf{B}_0$, $\angle(\mathbf{b}, \mathbf{B}_0) = 45^\circ$ at $T = 40$ K showing the gradual appearance of cross peaks with increasing mixing time

and $a_{AA} = a_{BB}$, equation (33a) can be rewritten as

$$R(t_m \rightarrow \infty) = \frac{1 - q}{1 + q} \quad (34)$$

A measurement of $R(t_m \rightarrow \infty)$ thus allows for a determination of q in the slow motion limit.²³

The time evolution of $R(t_m) = a_{BA} / a_{AA}$, on the other hand (Figure 18), allows for a direct site specific measurement of

Figure 18 Ratio of cross peak to diagonal peak intensity R as a function of the mixing time t_m at $T = 40$ K. The same curve is obtained for different crystal orientations with different ω_{AB} splittings so that spin diffusion is excluded

the deuteron intra-hydrogen bond exchange rates, $A \rightarrow B$:

$$R(x) = \tanh x \quad x = t_m / \tau \quad (35)$$

The observed intra-hydrogen bond deuteron exchange times²³ vary from 14.4 s at $T = 45$ K to 235 s at $T = 24$ K. The motion is thermally activated with $E_a = 12.8$ meV and $\tau_0 = 0.43$ s, showing that phonon assisted deuteron tunneling may be important.

6 NMR DETERMINATION OF ORDER PARAMETERS IN INHOMOGENEOUS FERROELECTRICS

For $0 \leq x < x_{FE}$ or $x_{AFE} \leq x \leq 1$ (see Figure 2) where $|J_0| > J$ a long-range ordered inhomogeneous ferroelectric or antiferroelectric phase exists below T_c . Here long-range and glassy order should coexist below T_c . Above T_c , long-range order vanishes whereas glassy order should persist. The glassy state is characterized above T_c by the Edwards–Andersons parameter q_{EA} and below T_c by $\tilde{q}_{EA} = q_{EA} - P^2$, i.e. by the difference between the EA order parameter and the square of spontaneous polarization P^2 . Both $\tilde{q}_{EA}$ and q_{EA} have been determined²⁵ by ^{75}As NQR ($T < T_c$) and quadrupole perturbed NMR ($T > T_c$) in $\text{Rb}_{1-x}(\text{NH}_4)_x\text{H}_2\text{AsO}_4$ for $x = 0.01$ and $x = 0.02$.

In pure RbH_2AsO_4 the experimentally measured temperature dependences of the spontaneous polarization $P = P(T)$ and the ^{75}As NQR frequency $\nu_Q(T)$ determine the relationship $\nu_Q = \nu_Q(P)$. In a mixed crystal in the weak disorder limit $x \rightarrow 0$ the $\nu_Q = \nu_Q(P)$ relation for the mean NQR frequency is the same as in the pure crystal. In the general case we replace the reduced spontaneous polarization $\bar{P} = P/P(T = 0)$ by the local polarization p . We thus have

$$\omega_Q = \omega_0 + \omega_2 p^2 + \omega_4 p^4 \quad (36)$$

Figure 19 Experimental and theoretical ^{75}As NQR lineshapes²⁵ in $\text{Rb}_{1-x}(\text{NH}_4)_x\text{H}_2\text{PO}_4$ for $x = 0.00$ and $x = 0.02$ for $T < T_c$

Figure 20 Temperature dependence²⁵ of q_{EA} and $\tilde{q}_{EA} = q_{EA} - P^2$ in $Rb_{1-x}(NH_4)_xH_2AsO_4$ for $x = 0.02$. Theoretical fits are shown as solid lines

as the ^{75}As NQR frequency is invariant with respect to the sign reversal of p . The temperature dependence of the mean ^{75}As NQR frequency thus yields the long-range order parameter P whereas the inhomogeneous ^{75}As NQR lineshape yields the local polarization distribution function $W(p)$, and its second moment q_{EA} , via

$$f(\omega) = W(p)|d\omega/dp|^{-1} \quad (37)$$

The ^{75}As pure NQR lineshapes of $Rb_{1-x}(NH_4)_xH_2AsO_4$ for $T < T_c$ are shown in Figure 19 for $x = 0.00$ and $x = 0.02$ together with the theoretical fits obtained from the compressible random bond–random field pseudospin Ising model.²⁵ In contrast to the case of proton and deuteron glasses ($|J_0| < J$) the local polarization distribution function $W(p)$ is asymmetric with respect to $p = 0$ here.

The temperature dependence of q_{EA} and $\tilde{q}_{EA} = q_{EA} - P^2$ for $x = 0.02$ is shown in Figure 20. The theoretical fits are shown as solid lines. The jump in q_{EA} at T_c demonstrates the occurrence of a first-order phase transition.

Theoretical fits demonstrate that random bond effects dominate random field effects thus proving the existence of a collective glassy state in inhomogeneous ferroelectrics even in the weak substitutional disorder limit.

1 INTRODUCTION

I believe it was in 1950, when I first met Ed Purcell at the Amsterdam conference on rf spectroscopy, that I heard him mentioning nuclear ferromagnetism as a very interesting phenomenon, but inaccessible in the present state of cryogenic techniques. Since then I had been thinking about it from time to time but it was only after I discovered dynamic nuclear polarization (DNP) in solids, a method that I shall describe shortly, that I had an inkling of the key to the problem.

To understand what nuclear ferromagnetism, or more generally, any long-range nuclear order, is like, one should first recall the nature of the external order introduced in a system of nuclear spins by an external magnetic field—the so-called Zeeman order. This is the kind of order which exists in the classical nuclear magnetic resonance (NMR) experiments. A nuclear spin placed in a magnetic field tends to align the magnetic moment that it carries along that field, that is into a position of lowest energy. However, when embedded into a piece of bulk matter, the nuclear spins are continually disoriented through thermal agitation. Between the orientation caused by the magnetic field and the disorientation due to thermal agitation, a compromise is reached where the nuclear polarization is of the order of the ratio $\mu \cdot H/kT$ of the magnetic energy of a nuclear magnetic moment μ in a field H to the thermal energy kT . For protons at room temperature, this ratio is on the order of a few parts in a million in a field of 1×10^4 Oe which, however, is quite adequate for classical NMR (and of the order of a few parts in a billion in the Earth's magnetic field), but it is possible, using DNP, to reach polarizations close to unity.

If there is no external field, what are the conditions for the existence of a long-range order—say, ferromagnetic—of nuclear spins? It should occur when the energy of a single spin, resulting from its interaction with the surrounding spins, is not small compared with the thermal energy kT . A crude estimate can be made as follows: at the site of each nucleus exists a local magnetic field H_L , produced by its neighbors. It is on the order of a few gauss for protons and smaller for other nuclear species. One can guess that, for a long-range order to exist, the ratio $\mu \cdot H_L/kT$ of the magnetic energy of each spin

in the local field H_L to the thermal energy kT should be at least of order unity. With a local field H_L of a few gauss and the μ of the proton, this yields temperatures below $1 \mu K$ —no wonder that Purcell considered it to be below the cryogenic possibilities of the day.

Before discussing the means for reaching this goal, I would like to illustrate the difference between a Zeeman order—induced by an external field—and an *internal* order—induced by interactions between the spins, through an image, suggested perhaps by my acquaintance with two learned societies, the Royal Society of London and the Pontifical Academy of the Vatican.

Imagine a Roman crowd massed in St Peter's Square, being addressed by the Supreme Pontiff from a window in the Vatican. All eyes in this crowd are turned towards that window and also, inevitably, all the noses which we shall choose as vector models of the spins. All the noses are therefore parallel to each other (neglecting the small effect of parallax). We have here a Zeeman order of noses, induced by the external 'pontifical field' which is the pontifical presence at the window.

Now imagine the same Roman crowd, already massed in the square half an hour before the Pope is due to appear at his window. They have no particular reason to look towards a window where the Pope will not appear for another half an hour, and one might think that their noses are orientated entirely at random. To see how an internal order of the noses may conceivably appear, we have to make a few plausible assumptions about interactions. We shall assume (not an unrealistic assumption) that these Romans are fond of eating garlic, which they consume in large quantities, but that they relish the taste of the garlic in their own mouths more than its smell on their neighbor's breath. There will be, for each Roman nose, a trend towards avoiding his neighbor's face and turning preferentially towards his back, which makes this nose parallel to his neighbor's nose. There is a 'ferromagnetic' coupling between their orientations. Does it mean that all the noses in the square will be parallel to each other? Not quite.

This, as I said, is a Roman crowd, warm and lively. They exchange jokes and comments, they fidget, they jostle each other, and no nose keeps the same orientation for any length of time. Furthermore their dislike of the smell of garlic exhaled by their neighbors is slight. It is a case of a weak interaction and a high temperature. There will be a short-range order where two neighboring noses tend to be parallel, but this order will not spread over a large distance, and there will be no correlation between the orientation of two noses, say 20 ft apart.

Now picture a crowd of English gentlemen (an endangered species, I was told but a recent stay in an Oxford college has convinced me that this is not so; the species is thriving) *unacquainted with each other*, who naturally would not dream of eating garlic. They are, however, mortally afraid of being spoken to by people to whom they have not been introduced. There will be a strong incentive for each of them to stare at a neighboring back, with again a ferromagnetic arrangement of the noses, caused by a ferromagnetic interaction which is much stronger than with my Romans. Furthermore, this is a *cold* crowd. They do not fidget and jostle each other, and every English nose keeps the same orientation for a long time. There is a strong interaction and a low temperature; there will be a long-range order, and two English noses many yards apart will be parallel to each other.

The ferromagnetic order of spins is not the only one which exists in nature: with electronic spins, an antiferromagnetic order was observed more than half a century ago; this is where the two nearest neighbors are antiparallel. (The reader may, if he or she so wishes, imagine what kind of food would induce an antiferromagnetic arrangement in the model of the Roman crowd.)

The frivolous analogy between an assembly of spins and the Roman crowd can be pushed a little further. In the Zeeman order, the external ‘pontifical field’ acts on the eyes rather than on the noses of the Romans and, if it orients the noses, it is indirectly because they are anatomically parallel to the direction of the eyes. On the other hand, in the internal order it is the noses themselves which are responsible for the orientation in the ‘garlic’ model.

The same thing happens in ferromagnetic ordering of electronic spins. Each spin carries a magnetic moment collinear with it, which is the analog of the parallelism between the eyes and the noses of the Romans. In the Zeeman order, an external magnetic field applied to a ferromagnetic substance will act on the *magnetic moments* rather than on the spins, and the spins will follow because they are collinear with the magnetic moments. On the other hand in the internal order it is the spins themselves which are responsible for the ferromagnetic ordering through a nonmagnetic quantum-mechanical exchange coupling and it is the magnetic moments which follow suit.

In nuclear ordering, the exchange coupling between spins does not exist (with the exception only of ^3He which is not considered here). There is no other coupling between nuclear spins but magnetic, and at least for light nuclei it has a well-defined mathematical form—the so-called dipolar form—and a magnitude which is entirely determined from the values of the magnetic moments and the interatomic distances, all of which is very well known. Everything in nuclear dipolar order can thus be calculated entirely, at least in principle if not in practice; it is a ‘clean’ problem. It was these twin aspects, the cleanliness and the arduousness (something like the snowy purity of a Himalayan summit), which for many years attracted me and my co-workers in this quest. But before going any further it is necessary to explain the means which made this quest possible, namely the DNP.

2 DYNAMIC NUCLEAR POLARIZATION

Consider a solid insulator containing nuclear spins I and at a much smaller concentration, say one part in a few thousands, electronic spins S . Assume conditions of field and temperature, say 2.5×10^4 Oe and 1 K, such that the spins S are completely polarized, say all pointing ‘up’, and the nuclear spins, with their magnetic moments thousands of times smaller, almost completely unpolarized, as many ‘up’ as ‘down’.

Assume also that the spin–lattice relaxation time of the spins S is very short so that, if through any circumstance a spin S happens to flip to the ‘down’ position away from equilibrium, its relaxation mechanism will bring it very rapidly back to the ‘up’ position. All these assumptions are quite realistic. The DNP problem is to bring all the nuclear spins to the ‘up’ position.

Consider a nuclear spin which is ‘down’. It could come ‘up’ by making a flip-flop with an electronic spin which is ‘up’.

This requires an energy $\Omega = \Omega_S - \Omega_I$ which in a liquid could be borrowed from the kinetic energy of the relative motion of the two spins, but which is lacking in a rigid lattice. This energy can be provided to the spins by means of an external microwave source of frequency Ω , driving a flip-flop which brings the spin I ‘up’ and the spin S ‘down’. However, the spin S which has come ‘down’ returns immediately to its equilibrium ‘up’ position because of its fast relaxation time. The spin I , which has come ‘up’, ‘sees’ around it only spins S also pointing ‘up’ with which it cannot flip-flop. It might flip-flop, however, if the energy for it ($\Omega_S + \Omega_I$) were available, but it is not, and so the spin I stays ‘up’. All the spins I are thus, one by one, brought into the ‘up’ position.

The extreme assumption of a 100% polarization of the spins S , made for simplicity, is by no means necessary; it can be shown that, whatever the electronic polarization, this method in principle permits nuclear polarization to become equal to it.

An identical argument shows that, if the sample is irradiated with the flip-flop frequency $\Omega = \Omega_S + \Omega_I$, this will impart a polarization to the nuclear spins which is equal but opposite to the electronic polarization.

One should stress the importance of the fast relaxation of the spins S . Each of the spins S has to ‘service’ thousands of spins I . No sooner has it flip-flopped with a spin I than it has to come back into the position ‘up’ to ‘service’ another spin I . This fast relaxation calls for qualities, whose human analog led me sometimes to call this effect the ‘King Solomon method’.

3 THE KEYS TO THE PROBLEM

The keys to the problem are DNP and the spin temperature. The first produces an almost perfect Zeeman order of the nuclear spins, and the second a ‘cooling’ of the nuclear spins to temperatures required for the production of a long-range order—a microkelvin or less—replacing the ‘external’ Zeeman order by an ‘internal’ dipolar order.

In fact the concept of spin temperature can advantageously be replaced by that of entropy, for which it is enough to remember here that it is a quantitative measure of the order existing within a system. The entropy is zero if the order is perfect and has its maximum value in a situation of complete chaos. By producing an almost perfect Zeeman order, one reduces the system’s entropy to nearly zero, or at least to a value lower than the critical entropy, which is the value below which long-range order appears. The next step is to suppress the applied field very slowly and reversibly (adiabatically is the technical term), taking care to introduce as little new disorder as possible in the process, that is an increase in entropy which is as small as possible. During this ‘adiabatic demagnetization’ as it is called, the external Zeeman order turns progressively into an internal dipolar order. (The Roman analog of adiabatic demagnetization would be the disappearance of the Pope from his window, very gradually and very slowly, something like the Cheshire cat.) There is one practical difficulty connected with adiabatic demagnetization. Considering the weakness of nuclear magnetic moments, NMR is still to a large extent the only method for observing their behavior, but NMR is only observable in a high magnetic field. By reducing this field to zero in an adiabatic demagnetization, one may perhaps be creating an ordered state of the spins but, in the same move,

one deprives oneself of the possibility of making sure of its existence. It is not unlike trying to find out whether the lamp in a refrigerator goes off when one closes the door. I am now going to digress to explain the nature of the rotating frame, a concept familiar to NMR users, and how it may solve what I call the problem of the 'refrigerator lamp'.

4 THE ROTATING FRAME AND THE REFRIGERATOR LAMP

Use of the rotating frame makes it possible to '*have your cake and eat it*', that is to transfer the Zeeman order which has been created by DNP in a high field $\mathbf{H}$ to the dipolar spin-spin interaction, while keeping on that high field for observing the state of the spins by NMR.

The difficulty resides in the fact that the Zeeman energy is quantized in quanta of the order of, say, a hundred megahertz, whereas the energy spectrum of the dipolar energy does not extend beyond some hundred kilohertz. In high fields the two systems are not 'on speaking terms'. It is, however, possible to ensure a flow of energy and thus also of entropy between them, by providing the dipolar system with the energy that it lacks to 'speak' to the Zeeman system in the form of rf quanta which are brought in by an rf field, rotating at a frequency Ω near the Zeeman frequency Ω_0 .

One of the two frequencies (the Zeeman frequency Ω_0 in general) is swept slowly (adiabatically), from a value distant from Ω all the way to Ω , that is to resonance. At resonance most of the entropy contained in the disordered dipolar system passes on into the Zeeman system or, in other words, most of the Zeeman order passes on into the dipolar system. Then, after the rf field is cut off, the two systems are again isolated from each other. One might think that the presence of the high magnetic field can be forgotten. Not quite. Although the cutting off of the rf field suppresses the flow of energy (and entropy) between the Zeeman and the dipolar system, it can be shown (we shall not do so here) that, simply by being present, the high magnetic field splits the dipolar spin-spin interaction into two parts. Only one of them, the so-called 'truncated' part, is effective in the presence of the high applied field.

The form of this truncated part depends on the orientation of the applied magnetic field with respect to the crystalline axes of the sample—which is a very essential fact.

The above presentation can be put on a more quantitative basis by introducing the concept of the 'rotating frame'. To describe the behavior of the spins in the presence of a rotating field, it is convenient to choose as a frame of reference, one which rotates with the angular velocity of Ω of the field; this is the 'rotating frame'. In that frame the rotating field of amplitude $\mathbf{H}_1$ orthogonal to the applied field $\mathbf{H}$ appears as a static field of magnitude H_1 , which is much simpler. On the other hand, since the new frame is rotating, it is not an inertial frame any longer, and an inertial force must be brought in. It can be shown that this is equivalent to replacing the large applied field $\mathbf{H}$ by a fictitious field $\Delta\mathbf{H} = \mathbf{H} - \mathbf{H}^*$, where $\mathbf{H}^*$ is the value of $\mathbf{H}$ at exact resonance, when the Zeeman frequency Ω_0 has been made equal to Ω . In the rotating frame the spins 'think' that they 'feel' an effective field $\mathbf{H}_e$ which is the geometrical sum of the two static fields $\Delta\mathbf{H}$ and $\mathbf{H}_1$ orthogonal to each other.

The opening of the flow of entropy between the Zeeman and the dipolar systems is called adiabatic demagnetization in the rotating frame (ADRF). Far from resonance, $\Delta\mathbf{H}$ is much larger than $\mathbf{H}_1$ and the effective field $\mathbf{H}_e$ is almost parallel to the applied field $\mathbf{H}$, and thus also to the equilibrium magnetization $\mathbf{M}$. In the course of the ADRF this magnetization 'follows' the effective field which moves increasingly farther away from the direction of $\mathbf{H}$ until, at exact resonance, where $\Delta\mathbf{H}$ vanishes, $\mathbf{H}_e$ reduces to the rf field $\mathbf{H}_1$. The ADRF is then brought to an end by removing the field $\mathbf{H}_1$.

One should note that, if the ADRF is started from the other end of the resonance where $\Delta\mathbf{H} = \mathbf{H} - \mathbf{H}^*$ is *antiparallel* to $\mathbf{H}$, one starts from a situation where the equilibrium magnetization $\mathbf{M}$ is *antiparallel* to the effective field $\mathbf{H}_e$, that is from a state of *negative* temperature. This sign does not change as the ADRF proceeds and leads to a dipolar state of negative temperature.

Besides solving the problem of the 'refrigerator lamp', ADRF brings new and fascinating variations on the conventional theme of dipolar order. Two different orientations of the applied field with respect to the crystalline axes correspond to two different ways of truncating the dipolar interaction and two, qualitatively different ordered structures. Furthermore, for a given orientation of the field, the two signs of the spin temperature must correspond to quite different structures since at negative temperatures a stable structure of the spins is one which *maximizes* the energy. The nuclear magnetic order is thus very much richer than the classical electronic order. As an example, we shall single out for description, in the following, two such ordered states.

Naturally the lifetime of a state where the spins are at a positive or negative temperature, whose absolute value is millions of times lower than the lattice temperature, is limited by the spin-lattice relaxation time T_d (the subscript d referring to dipolar) which, for reasons that would be too long to discuss here, is shorter by several orders of magnitude than the Zeeman relaxation time T_1 . Yet these times T_d may sometimes reach values of the order of 1 h, making the study of such ordered states possible.

5 ANTIFERROMAGNETISM IN CALCIUM FLUORIDE

The first substance chosen for the observation of nuclear magnetic order was a single crystal of calcium fluoride (CaF_2) where the nuclei of ^{19}F which have a spin- $\frac{1}{2}$ form a simple cubic lattice and the calcium nuclei, apart from a rare isotope ^{43}Ca , have zero spin. Since the ordered structures obtained by ADRF depend on the orientation of the magnetic field with respect to the crystalline axes, it is imperative to use single crystals. I pass over the different difficulties encountered in building the equipment, choosing the adequate impurities for doping the crystal, and, on the theoretical side, calculating the structures to be expected and the critical nuclear polarizations to be obtained before ADRF.

The first observation of an antiferromagnetic nuclear state was made in CaF_2 with an initial polarization higher than 60%, a negative temperature, and a field $\mathbf{H}$ applied along a *fourfold* axis of the cube. As predicted by theory, one observed a characteristic plateau in the transverse magnetic susceptibility

Figure 1 Antiferromagnetic ordered structure of the ^{19}F spins in CaF_2 with the field along the (001) axis and with a temperature less than 0 K. The ^{43}Ca spins all ‘see’ the same local field produced by the fluorines. (Light arrows for the spins of ^{19}F , heavy arrows for the spins of ^{43}Ca which act as probes)

as a function of the dipolar energy of the fluorine spins. The structure is the Néel two-sublattices model, where the nuclear spins of the successive atomic planes are alternately parallel and antiparallel to the field. The structure is shown in Figure 1. The spins of the sublattice A, which are parallel to the field, yield a positive signal, and those of the second sublattice B a negative signal. They do not cancel each other because they are displaced with respect to each other by internal mean fields which have opposite signs in the two sublattices, as shown below in Figure 3(a). (For the reader familiar with NMR techniques, this is not the *derivative* of the resonance curve!)

6 FERROMAGNETISM IN CALCIUM FLUORIDE

Theory predicts a ferromagnetic state in the same crystal, again at negative temperature, for a field applied along a *threefold* axis of the cube. This ferromagnetic structure is made up of ferromagnetic domains, which are slabs perpendicular to the applied field, each some hundred atomic planes thick, where nuclear spins in the successive *slabs* are alternately parallel and antiparallel to the field, as shown in Figure 2. It is easy to convince oneself that the NMR signal of the fluorine spins [see Figure 4(a)] should look very much the same as in the antiferromagnetic structure in Figure 3(a).

The problem of discriminating between the two structures where the fluorine spin signals are almost indistinguishable from each other, can be solved because of the existence of ^{43}Ca , a rare (0.13%) isotope of calcium with a small magnetic moment, which serves as a probe. In the antiferromagnetic structure of the fluorine spins, all the positions of a calcium nucleus are equivalent (Figure 1) and all the spins of ^{43}Ca ‘see’ the same mean field produced by the fluorine atoms whereas, in the ferromagnetic domain structure, spins of ^{43}Ca , situated in domains of opposite signs, ‘see’ opposite mean fluorine fields (Figure 2). The Zeeman NMR signal of ^{43}Ca is thus a single line in the antiferromagnetic structure and a double line in the ferromagnetic case (Figure 4)—indisputable experimental evidence of the difference between the two structures. (This, in my view, is still one of the cutest experiments in NMR.)

7 CALLING UP NEUTRONS

For many years, neutron diffraction has been a valuable tool in the study of *electronic* antiferromagnetism. This can

Figure 2 Domain ferromagnetic structure with the field along the (111) axis and with a temperature less than 0 K. The ^{43}Ca spins in opposite domains (heavy arrows) ‘see’ local fields of opposite signs

be understood by comparison with X-ray diffraction. When an X-ray beam impinges on a crystal, for certain orientations of the beam with respect to the atomic planes of the crystal, there is constructive interference between the X-photons scattered by the different atoms of the crystal, and sharp maxima of diffracted radiation, called Bragg peaks, are observed in certain well-defined directions. If the crystal is antiferromagnetic, the magnetic moments of its atoms will have opposite orientations in two neighboring atomic planes. The scattering amplitude of an X-photon on a magnetic atom is independent (almost) of the orientation of its atomic moment and the X-photon is unable to ‘distinguish between’ two such planes.

On the contrary, the neutron which carries a magnetic moment will have different scattering amplitudes on two magnetic atoms with opposite moments. It will ‘see’ two neighboring atomic planes of an antiferromagnet as being different, and it will ‘deduce’ a lattice period twice as large as the crystalline period. The Bragg condition applied to this new period will give rise to new Bragg peaks when an antiferromagnetic state sets in (Figure 5).

It was naturally tempting to seek from neutrons the same tangible evidence for the existence of *nuclear* antiferromagnetism. This was even more tempting because reports of the antiferromagnetic structure described in Figure 1 were, at first, met with incredulity. The objection offered to me when I first reported it at an international conference was that the structure that I described could not exist because it *maximized* the energy of the spins, and my reply that this was indeed expected of a system at a negative temperature, did not convince everybody.

The objection to the use of neutrons for studying nuclear antiferromagnetism (which was also offered to me when I first made this suggestion) was the smallness of the nuclear magnetic moments which would prevent the observation of antiferromagnetic Bragg peaks. There is, however, a way out. The scattering of a neutron by a nucleus is due to a *nuclear* force and its amplitude depends on the relative orientation of the spin of the neutron and the spin of the nucleus. The scattering amplitude will be different for

Figure 3 Antiferromagnetic structure: (a) NMR line of ^{19}F ; (b) a single Zeeman NMR line of ^{43}Ca as explained in the text

two nuclei with opposite spins. The neutron spin is thus capable of distinguishing between two nuclear spins with opposite orientations, not through a magnetic interaction with their magnetic moments but through a *nuclear* interaction with their spins. The neutron is therefore able to recognize the difference between two planes with opposite nuclear orientations and is thus capable in principle of detecting nuclear antiferromagnetism. It is convenient to pretend that this 'recognition' is of a *magnetic* nature by assigning to each nuclear species a fictitious magnetic moment which is called its 'pseudomagnetic' moment and is represented by the symbol

Figure 4 Domain ferromagnetic structure: (a) NMR line of ^{19}F , indistinguishable from the NMR line in Figure 3(a); (b) a Zeeman line of ^{43}Ca with two peaks, as explained in the text

Figure 5 Normal and antiferromagnetic scattering of a neutron by an antiferromagnetic lattice (schematic). Dashed lines refer to normal scattering, full lines to antiferromagnetic scattering

μ^* . By definition, this pseudomagnetic moment is equal to the magnetic moment that a nucleus should possess in order that its *magnetic* coupling with the *magnetic* moment of the neutron be equal to the actual nuclear coupling, which exists between the spin of the neutron and the spin of the nucleus.

Nuclear forces are much stronger than magnetic forces, and there is reason to believe that a nuclear pseudomagnetic moment of the nucleus would be much larger than its true magnetic moment. It is certainly so for the proton whose pseudomagnetic moment $\mu^*(^1\text{H})$ is 3500 times larger than its real magnetic moment. Unfortunately $\mu^*(^{19}\text{F})$, once measured, turned out to be only 15-times larger than its true magnetic moment (and of opposite sign). This was far too small to observe the antiferromagnetic structure of CaF_2 and we decided to move on to a crystal containing protons, namely lithium hydride (LiH). It was not an easy task since it was only after four years of work that we were able to observe for the first time by neutron diffraction our first antiferromagnetic Bragg peak in LiH.

I shall omit here all the difficulties that we ran into during these four years, not the least of which was the fact that, unlike CaF_2 , LiH is a nasty crystal, hard to grow, to dope in a reproducible way and to handle. I shall be content to describe briefly the decisive experiment where the antiferromagnetic neutron Bragg peak was first seen.

The neutron counter for diffracted neutrons had been placed in the position where the antiferromagnetic Bragg peak was expected and the nuclei of the sample were dynamically polarized above the calculated critical polarization. The counter started to count background neutrons, as expected, since the sample was not *antiferromagnetic yet*. Then the ADRF was performed. The counting rate made a jump which corresponded to the expected antiferromagnetic peak and then decreased slowly to background level with a time constant of the order of an hour, while the entropy of the nuclear spins slowly grew as a result of relaxation until it reached the critical value above which the antiferromagnetic order disappears (Figure 6). It was one of the finest hours in our laboratory.

Need I add that diffraction experiments with LiH were pursued, improved, amplified, compared with theoretical predictions, and reported at numerous international conferences. Figure 7 shows one such result. I last spoke of it in 1986 at the Royal Society in my Claude Bernard Lecture (from which the figures are taken).

Figure 6 Sudden surge of an antiferromagnetic Bragg line, just after adiabatic demagnetization in the rotating frame, and its slow decay with the lifetime of an antiferromagnetic state. Produced in LiH, at $T < 0$ K, with the field along the (001) axis

Figure 7 Normal Bragg reflection line in LiH (left) with unpolarized spins and antiferromagnetic reflection line (right) at negative temperature with the field along (001). Scattering angle along the x axis, neutron counts along the y axis

Lest the reader should be led to conclude from the examples offered so far that *positive* temperatures have no physical existence, Figure 8 shows the same type of experiment as in Figure 6, but with a positive spin temperature.

An amusing contrast can be drawn between electronic and nuclear antiferromagnetism and their study with neutrons. It is well known that electronic antiferromagnetism is caused by exchange interactions between electronic *spins* which are

Figure 8 Same as Figure 6 but at a *positive* temperature $T > 0$ K

of a *nonmagnetic* nature. On the other hand its observation by neutron diffraction rests on the existence of *magnetic* interaction between the *magnetic* moments of the neutrons and the electrons. To sum up, we have a *nonmagnetic* phenomenon detected by *magnetic* means.

On the other hand, nuclear antiferromagnetism is a purely *magnetic* phenomenon due to *magnetic* interactions between nuclear *magnetic* moments, but its detection by neutrons rests on a nuclear, and therefore *nonmagnetic* interaction (termed for that reason pseudomagnetic) between nuclear spins and neutron spins. This is a purely magnetic phenomenon, detected by nonmagnetic means. ‘So what?’, one may ask. ‘So nothing; it’s an amusing contrast, that’s all.’

At the end of a lecture on nuclear magnetic order (I have given more than one), I used to speculate on the question: ‘What future for nuclear magnetic order?’ I would not do this any longer. But it has a nice past.

I cannot conclude without mentioning that the Finnish school headed by Professor Lounasmaa has worked for many years on the production and observation of nuclear magnetic order in metallic copper. Their approach and their methods were very different from ours. They worked on a metal (copper) and used ‘brute-force’ polarization and demagnetization in the laboratory frame. We worked on insulators and used dynamic polarization and demagnetization

in the rotating frame. Whichever method is better, one thing is certain: we got there first.

1 INTRODUCTION

Fast ion conductors (FICs) are generally defined as solids with ionic conductivity comparable to that found in liquids, typically $1\text{--}10\text{ S m}^{-1}$, with often an unusually low activation energy for ionic motion, $E \propto 10\text{ kJ mol}^{-1}$.¹ The terms ‘solid electrolyte’ and ‘superionic conductor’ are also widely used, and the related field of interdisciplinary research is known as ‘solid state ionics’. Concerns about environmental pollution and depletion of oil resources stimulated interest in FICs because of their potential use in rechargeable batteries. Interest has been sustained by the promise of other practical applications including fuel cells, chemical sensors and electrochromic displays, and by a desire to gain a better fundamental understanding of the unusual dynamic properties of these materials.

FICs are very diverse but can be divided roughly into two groups: crystalline and amorphous.² The crystalline materials include ionic crystals, e.g. AgI, RbAg₄I₅, and PbF₂, and covalent, layer- and tunnel-structured crystals, usually oxides, e.g. β -aluminas, Li₃N, and LiAlSiO₄. The amorphous materials include organic polymers, e.g. poly(ethylene oxide) doped with lithium triflate, and inorganic glassy systems, e.g. AgI–Ag₂O–B₂O₃ and Li₂S–SiS₂.

X-ray and neutron diffraction are the primary tools used in structural determinations of FICs. Conductivity measurements are routinely made to investigate the mechanisms of ion transport. Tracer diffusion is of very limited applicability, owing to the high diffusion coefficients of FICs, but quasielastic neutron scattering and NMR have provided experimental information about the ionic motion at a microscopic level (see also *Diffusion in Solids*). The motion of the ions can be simulated using computer modeling techniques such as molecular dynamics (MD).

NMR has always played an important role in solid state ionics, contributing considerably to the understanding of several FICs.^{3–9} NMR parameters that are used to probe the dynamic properties of FICs include linewidths and lineshapes and their temperature-dependent narrowing, nuclear spin–lattice and spin–spin relaxation times, and direct measurement of the diffusion coefficient by the pulsed field gradient technique and solid state NMR imaging. Protons, ⁷Li, ¹⁹F and ²³Na have been the most popular NMR probes. The information available from these studies includes the type

and number of mobile ions, the prefactor, activation energy and activation volume of these motions, and dimensionality, correlation and cooperative effects. Some of the most useful information comes from relaxation time measurements because these studies provide correlation times and, in favorable cases, correlation functions that can be related to microscopic processes.

Relaxation data for FICs often deviate strongly from the well known Bloembergen–Purcell–Pound (BPP) model. The most obvious difference is that the $\ln T_1$ vs $1/T$ plot is not symmetrical about the T_1 minimum, suggesting that the correlation function is not a single exponential function of time. Taking into account that the ions hop over a discrete one-, two-, or three-dimensional lattice, or may experience short-range interactions with each other, results in only small changes to the shape of the relaxation curve.

The simplest of several phenomenological approaches is to assume a distribution of relaxation rates with a distribution of activation energies for ionic motion. On the other hand, a homogeneous model with a single, but nonexponential, correlation function, such as the Kohlrausch–Williams–Watt (KWW) function (stretched exponential), can often fit the same observations. There have been several attempts to derive the KWW equation from first principles.

2 IONIC TRANSPORT

According to the classical model of atomic diffusion in solids, a mobile ion jumps over a potential barrier of height E (the activation energy) at a rate

$$\nu = \nu_0 \exp(-E/kT) \quad (1)$$

called the jump frequency.⁵ The ‘attempt’ frequency ν_0 is typically related to a vibrational frequency of the ion about its equilibrium position and comparable to a phonon frequency. By assuming that the ion undergoes uncorrelated jumps of length l at a rate ν , the diffusion coefficient can be expressed as

$$D = \nu l^2 / 2d \quad (2)$$

where d is the dimensionality of the system ($d = 1, 2, 3$). The hopping (or mean residence, or dwell) time $\tau_d = 1/\nu$ is assumed to be long compared with the transit (or flight time). The Nernst–Einstein equation gives the dc ionic conductivity as

$$\sigma = cq^2 D / kT \quad (3)$$

where c is the density of mobile ions carrying charge q . In FICs, in contrast to normal ionic solids, c is usually taken to be temperature-independent and equal to the mobile ion concentration.

The ratio of the directly determined diffusion coefficient (usually from tracer measurements) to that calculated from the conductivity, σ , via equation (3) is called the Haven ratio, H_R . H_R is not necessarily unity and is sensitive to the details of the diffusion mechanism. For a typical FIC, $\sigma \approx 10\text{ S m}^{-1}$ at 300 K, $c \approx 10^{28}\text{ m}^{-3}$, therefore $D \approx 1.6 \times 10^{-2}\text{ m}^2\text{ s}^{-1}$.

A typical jump distance, $l \approx 0.3$ nm, gives $\tau_d \approx 10^{-10}$ s. c and l must be known before ν can be calculated from the conductivity. One advantage of NMR is that it can often provide a direct estimate of ν .

3 NMR METHODS

NMR is particularly valuable in the field of FICs because of the information it can provide about ionic diffusion.^{3–7} The range of diffusion coefficients that are accessible to NMR methods is 10^{-20} – 10^{-8} m² s⁻¹, corresponding to hopping times in the range 1 – 10^{-12} s. A distinct advantage of NMR over some types of diffusion experiments, such as ionic conductivity or creep, is that the mobile ions in a multicomponent system are readily identifiable. It is possible to study materials in which the same ion diffuses by more than one process, and to distinguish between localized and long-range motion, and between bulk and surface effects. Low sensitivity is one disadvantage and another is that it cannot be used to study diffusion in paramagnetic systems, and even quite low levels of paramagnetic impurities can mask the effects of diffusion. NMR has been used to study atomic diffusion in other solids (see *Diffusion in Porous Media; Diffusion in Rare Gas Solids; Hydrogen–Metal Systems; Intercalation Compounds and Ultraslow Motions in Solids*).

3.1 Line Narrowing

At low temperatures where the ionic hopping time, τ_d , is long, the NMR lineshapes characteristic of the rigid lattice are observed. When τ_d becomes comparable to the inverse of the characteristic linewidth, $1/\delta\omega$, the linewidth narrows. For nuclei with spin of $\frac{1}{2}$, e.g. ¹H, for which the nuclear dipole–dipole interaction usually dominates, the rigid-lattice lineshape is a featureless bell shape, and appreciable narrowing occurs when $\tau_d < 10^{-4}$ s. For quadrupolar nuclei, e.g. ²H, for which the nuclear electric quadrupole interaction dominates, spectra may exhibit a series of well defined time-averaged lineshapes, with strongly distorted and attenuated spectra in intermediate regimes, before narrowing completely. Hopping times as short as the order of 10^{-7} s can be extracted from ²H NMR lineshape studies.

3.2 Nuclear Spin Relaxation

Nuclear spin relaxation (NSR) is caused by the time dependence of the spatial part of the Hamiltonian describing the spin–lattice interaction (see *Dipolar and Indirect Coupling Tensors in Solids, Internal Spin Interactions and Rotations in Solids and Relaxation: An Introduction*).^{3–5,10} The Hamiltonian is the product of a spin operator part and a ‘lattice’ function $F(\mathbf{r}(t))$. The spin operator part is treated quantum mechanically, while the lattice function is assumed to form a classical autocorrelation function (CF)

$$g(t) = \langle F(t)F^*(0) \rangle / \langle FF^* \rangle \quad (4)$$

The nuclear spin–lattice relaxation rate is given by

$$\frac{1}{T_1} = A\{j(\omega_0) + 4j(2\omega_0)\} \quad (5)$$

where $\omega_0 = -\gamma B_0$ is the resonance frequency.

A is proportional to the mean square interaction Ω_{SL}^2 , describing the strength of the coupling between the spin system acting as a probe for the motion of the ions and the ‘lattice’. In the case of the dipole–dipole interaction between two diffusing spins, $\Omega_{SL}^2 \propto M_2$, the Van Vleck second moment. For quadrupolar nuclei, e.g. ⁷Li, ²³Na, and ²H, if quadrupolar relaxation is dominant, $\Omega_{SL}^2 \propto \chi^2$, the square of the quadrupole coupling constant (*Relaxation Theory for Quadrupolar Nuclei*). In the case of heavy nuclei, e.g. ¹⁰⁹Ag, chemical shielding anisotropy is the dominant interaction; consequently $\Omega_{SL}^2 \propto \omega_0^2$. The spectral densities $j(\omega)$ are the real parts of the Fourier transforms of the CFs,

$$j(\omega) = \int_0^\infty g(t) \cos(\omega t) dt \quad (6)$$

The spin–spin relaxation time, T_2 , is given by

$$\frac{1}{T_2} = A\left\{\frac{3}{2}j(0) + \frac{5}{2}j(\omega_0) + j(2\omega_0)\right\} \quad (7)$$

This equation is valid only in the motionally narrowed regime when $T_2 \gg (\gamma B_{loc})^{-1}$, where B_{loc} is the local dipolar field. If spin–lattice relaxation occurs in the presence of a resonant rf field, B_1 , and $B_0 \gg B_1 > B_{loc}$, then its characteristic time, $T_{1\rho}$, is called the spin–lattice relaxation time in the rotating frame,

$$\frac{1}{T_{1\rho}} = A\left\{\frac{3}{2}j(2\omega_1) + \frac{5}{2}j(\omega_0) + j(2\omega_0)\right\} \quad (8)$$

where $\omega_1 = -\gamma B_1$.

In order to relate $j(\omega)$ to ionic diffusion, $g(t)$ must be calculated for a given mechanism of motion. In a rough approximation it is quite reasonable for a motional process to let $g(t)$ have the functional form

$$g(t) = \exp(-|t|/\tau_c) \quad (9)$$

where τ_c is the ‘NMR correlation time’ (*Brownian Motion and Correlation Times*). In general, τ_c differs from the mean residence time, τ_d , of the mobile ion. In the case of the motion of a spin pair, $\tau_c = \tau_d/2$. Furthermore, spatial and temporal correlation effects in the motion process influence the relationship between τ_c and τ_d . After carrying out the Fourier transform of equation (9), the NSR rate may be expressed as

$$\frac{1}{T_1} = A \left(\frac{\tau_c}{1 + \omega_0^2 \tau_c^2} + \frac{4\tau_c}{1 + 4\omega_0^2 \tau_c^2} \right) \quad (10)$$

Equation (10) is usually referred to as the ‘BPP’ equation, and similar expressions for T_2 and $T_{1\rho}$ may be obtained from equations (7) and (8), respectively. Although equation (10) is only an approximation, it provides a fair basis for describing the important general trends in a motion-induced relaxation

process. The main feature of the relaxation rates is that they peak at different correlation times. $1/T_{1\rho}$ has a maximum when $\omega_1\tau_c \approx 1$, so it is most sensitive to hopping rates $1/\tau_c \approx \omega_1 \approx 10^5 \text{ s}^{-1}$. On the other hand, $1/T_1$ peaks near $\omega_0\tau_c \approx 1$, i.e. for $1/\tau_c \approx \omega_0 \approx 10^9 \text{ s}^{-1}$. So the various relaxation rates can be measured to probe a wide range of ion hopping rates. Since $1/T_1$ is becoming small for $1/\tau_c \gg 10^9 \text{ s}^{-1}$ the maximum hopping rate that can be measured by NMR is determined by the point at which relaxation processes other than diffusion began to dominate. This is often determined by the level of paramagnetic impurities in the sample. The limiting forms of the BPP equation, for dipolar and quadrupolar relaxation, are

$$\frac{1}{T_1} = \begin{cases} \tau_c, & \omega_0\tau_c \ll 1 \\ (\tau_c\omega_0^2)^{-1}, & \omega_0\tau_c \gg 1 \end{cases} \quad (11)$$

If the temperature changes of τ_c can be described by a simple activation law, analogous to equation (1), both above and below the T_1 minimum, the slope of $\ln T_1$ vs $1/T$ yields the activation energy of the motion.

3.3 PFG Method

When diffusion is sufficiently fast ($D > 10^{-13} \text{ m}^2 \text{ s}^{-1}$), the diffusion coefficient can be measured by the PFG method.¹¹ This method is equivalent to a tracer experiment where the nuclear spin is used as a ‘label’ on the mobile ion. The position of a nuclear spin in a magnetic field gradient is ‘labeled’ by its Larmor frequency, $\omega_0(\mathbf{r})$. The method involves a modified Hahn spin echo experiment, in which the sample is subjected to a $\pi/2 - \tau - \pi$ pulse sequence with intense magnetic field gradient pulses applied between the two rf pulses and between the π pulse and the echo. If the spins move their positions during the interval between the two field gradient pulses, the echo is attenuated. The method provides a direct, model-independent measurement of D , and the measurement can be calibrated by determining the attenuation in systems with known diffusion coefficients. Compared with relaxation measurements, the PFG method is relatively unaffected by the presence of paramagnetic impurities.

3.4 NMR Imaging

In NMR imaging, images of the nuclear spin density or NSR rates are reconstructed from spectra recorded in the presence of magnetic field gradients.¹² The broad lines usually encountered in solid state NMR present considerable difficulties for imaging, especially for proton-containing solids, e.g. polymers. One successful approach to the problem is to narrow the lines artificially by multiple pulse narrowing or magic angle sample spinning (see also *Line Narrowing Methods in Solids*). For half-integral spins, such as ^{23}Na , the central, $\frac{1}{2} \rightarrow -\frac{1}{2}$, transition is relatively narrow, and the technique has been successfully used to image ^{23}Na diffusion in Na β -alumina (see also *Ceramics Imaging and Imaging Techniques for Solids and Quasi-Solids*).

4 CORRELATION FUNCTIONS

In many FICs the BPP model [equation (10)] is inadequate, as demonstrated by the following failures: (i) the $\ln T_1$ vs. $1/T$ plot is not symmetrical with respect to the temperature at which the T_1 minimum occurs; (ii) the value of E deduced from this plot does not agree with values obtained from conductivity data; (iii) the values of $1/\tau_c$ are not in the range of an optical phonon frequency; and (iv) on the low-temperature side, T_1 is not proportional to ω_0^2 .⁶ A great deal of effort has been expended over the past 20 years in trying to find better correlation functions.

4.1 Dimensionality of Motion

For both dipole–dipole and quadrupolar relaxation, $(1/T_1 \propto \omega_0^2\tau_c)^{-1}$ when $\omega_0\tau_c \gg 1$, independent of dimensionality. A dimensionality effect is expected in one- and two-dimensional systems at long times when the correlation functions decay more slowly.^{4,5} Thus for $\omega_0\tau_c \ll 1$

$$\frac{1}{T_1} \propto \begin{cases} (\tau_c/\omega_0)^{1/2}, & \text{for 1D} \\ \tau_c \ln(1/\omega_0\tau_c), & \text{for 2D} \\ \tau_c, & \text{for 3D} \end{cases} \quad (12)$$

4.2 Microscopic Correlation Functions

The first improvements were achieved by explicitly taking into account the discrete character of the crystal lattice and correlations between the motion of the ions. These and other three-dimensional models of hopping diffusion, which include short-range repulsions between the mobile ions, predict only small differences in the shape and width of the T_1 minimum compared with the predictions of the BPP model.^{4,5}

4.3 Phenomenological Correlation Functions

An obvious extension of the BPP model is to assume independent ionic hops over a distribution of barriers $f(E)$:

$$\frac{1}{T_1} = A \int_0^\infty \{j(\omega_0) + 4j(2\omega_0)\} f(E) dE \quad (13)$$

A Gaussian distribution often works well. This model is widely used to account for the asymmetry of the $\ln T_1$ vs $1/T$ curves.⁶

An alternative approach is to assume a stretched exponential, or Kohlrausch–Williams–Watts (KWW) function, for the correlation function of the form

$$g(t) = \exp[-(t/\tau_c)^\beta] \quad (14)$$

with $0 < \beta \leq 1$. The corresponding limiting T_1 behavior is

$$\frac{1}{T_1} = \begin{cases} \tau_c, & \omega_0\tau_c \ll 1 \\ \tau_c^{-\beta}(\omega_0)^{-\beta-1}, & \omega_0\tau_c \gg 1 \end{cases} \quad (15)$$

There have been several attempts to derive equation (14) from first principles. These include⁷ the ‘jump relaxation’ model, the ‘two-level system’ model, and the ‘diffusion-controlled relaxation’ model.

4.4 Graphical Determination of Spectral Density Functions

A graphical, temperature–frequency superposition technique, which is independent of any model of the motion, has been described for extracting the spectral density function, $j(\omega)$, and its temperature dependence from measurements of T_1 , T_2 , and $T_{1\rho}$.¹³ Using a simple, iterative tracing procedure, the results of relaxation measurements at different frequencies (ω_0 , ω_1 , 0, etc.) and different temperatures are superimposed to form a master curve, $j(\omega\tau_c)/j(0)$ vs. $\omega\tau_c$, a datum line, $j(0)$ vs. τ_c , and an Arrhenius plot, $\ln \tau_c$ vs. $1/T$. These graphs display all the statistical mechanical information contained in the data. The characteristic time, τ_c , is determined from the shape of the master curve.

5 EXAMPLES OF NMR STUDIES

5.1 Crystalline FICs

5.1.1 Solids with Phase Transitions

Relatively soft crystals, often containing large, polarizable, heavy mobile ions such as Ag^+ , Cu^+ , Hg^{+2} , Pb^{+2} , or Tl^+ , are members of this group.¹⁴ The transitions may be first order as in, for example, AgI , or diffuse, as in PbF_2 , and apparently all fluorite-structured compounds.

A good example is $\alpha\text{-RbAg}_4\text{I}_5$, which has the highest conductivity at room temperature, 27 S m^{-1} , of any FIC. The rubidium ions are immobile, and the 16 mobile silver ions per unit cell are disordered over 56 sites. The ^{87}Rb relaxation rate exhibits a critical behavior which is already present above the critical temperature T_c . In contrast, the ^{109}Ag relaxation rate shows only a small step-like increase in rate at T_c and indicates thermally activated hopping.¹⁵ PFG measurements, combined with measurements of electrical conductivity, show that the Haven ratio decreases from 0.52 to 0.39 at the $\alpha \rightarrow \beta$ transition, suggesting some type of cooperative mechanism for silver diffusion. The pressure independence of E for silver relaxation shows that the activation volume is about zero, in agreement with conductivity data.

There has been considerable debate on the nature of F^{-16} transport in fluorite-structured FICs. An early model was the molten sublattice concept. $\beta\text{-PbF}_2$ is best suited for study because it has the highest σ and lowest T_c of all the fluorides. The results of a relaxation study are shown in Figure 1. Values of the Haven ratio H_R deduced from studies of PFG and σ approach unity at the highest temperatures.¹⁷ The form of the spectral density function extracted from measurements of T_1 , $T_{1\rho}$, and T_2 by the graphical temperature–frequency superposition technique shows (Figure 2) only minor deviations from an exponential correlation function and good agreement with numerical calculations of $j(\omega)$ carried out assuming hopping over a face centered cubic lattice.¹³ Neither these results nor MD simulations support the molten sublattice model.

5.1.2 Heavily Doped and Massively Disordered Solids

High concentrations of dopants, typically 10–20 mol%, can produce high concentrations of mobile defects, as in Y^{3+} -doped CeO_2 , where the mobile defects are oxygen vacancies.

Figure 1 Relaxation rates of ^{19}F in pure polycrystalline $\beta\text{-PbF}_2$ as a function of reciprocal temperature. ν_0 is the Larmor frequency and B_1 is the rf field strength. (Reproduced by permission of Elsevier from Boyce et al.¹⁶)

Figure 2 Spectral density functions determined using the temperature–frequency superposition method¹³. The curve for $\beta\text{-PbF}_2$ was derived from the ^{19}F relaxation rates shown in Figure 1. The curve for Na β -alumina was derived from the ^{23}Na T_1 data shown in Figure 3

In a study of T_1 and T_2 in a ^{17}O -enriched sample, the non-BPP asymmetry of the T_1 minimum was well fitted by a model based on a wide distribution of activation energies for hopping.¹⁸

A study of T_1 , $T_{1\rho}$, and T_2 of ^{19}F has been carried out on RbBiF_4 .¹⁹ This massively disordered compound has a fluorite structure with a disordered distribution of rubidium and bismuth atoms over the cation sites and high levels of F^- interstitials. The fluoride ions migrate by the interstitialcy mechanism, and the NMR results show that there is fast exchange between the two fluoride sites.

5.1.3 Layer- and Tunnel-Structured Materials

The celebrated ceramic materials β - and β'' - Al_2O_3 have mobile cations located in conduction planes between spinel-structured alumina blocks (see also *Ceramics*).⁷ Sodium-23 spectra²⁰ recorded at low temperatures show evidence of the multiple sites for sodium ions thought to be present from X-ray diffraction studies. Diffusion is sufficiently fast to average these lines to a single peak at only 100 K. The lineshape is characteristic of an asymmetric time average electric quadrupole coupling tensor up to at least 500 K, which is consistent with the motion of the sodium ions being restricted to two dimensions. Measurements of T_1 (Figure 3) show a highly asymmetric minimum, which was analyzed assuming a distribution of activation energies.²¹ On the other hand, the spectral density function obtained from the same data by the temperature–frequency superposition method (Figure 2) is consistent with a single activation energy.¹³ Below the T_1 minimum, $j(\omega) \propto \omega^{-1.4}$, which is similar to the behavior found for other two-dimensional systems (*Intercalation Compounds*).

Li_3N is possibly the best known lithium ion conductor, with $\sigma = 10^{-1} \text{ S m}^{-1}$ at 320 K. The Li_3N structure consists of pure

Figure 3 Spin–lattice relaxation T_1 of ^{23}Na in crystals of $\text{Na } \beta$ -alumina as a function of reciprocal temperature. $\text{Li}(1)$ layers alternating along the hexagonal c axis linked by layers of Li_2N in which $\text{Li}(2)$ is hexagonally coordinated to N^{3-} . As might be expected, σ is anisotropic. The intralayer and slower interlayer diffusion was investigated by ^7Li and ^6Li NSR and by the PFG method.⁶

The mineral β -eucryptite, LiAlSiO_4 , and materials of the hollandite type have fractionally occupied one-dimensional tunnels. T_1 measurements on ^7Li , ^6Li , and ^{27}Al are consistent with one-dimensional intratunnel and interchannel diffusion processes.⁶

5.1.4 Proton Conductors

Hydrogen uranyl phosphate hydrate, $\text{HUO}_2\text{PO}_4 \cdot 4\text{H}_2\text{O}$ (HUP), is one of the best examples of the hydrated proton conductors, with $\sigma = 4 \times 10^{-1} \text{ S m}^{-1}$ at room temperature. It undergoes a transition at 274 K to a low-temperature, poorly conducting phase. Planar acidic, hydrogen-bonded networks containing equal numbers of H_4O_2 and H_5O_2^+ dimers are located between $(\text{UO}_2\text{PO}_4)_n^{n-}$ layers.² Whether the protons move by a Grotthus-type mechanism in which protons move by a combination of reorientations of H_4O_2 dimers and hopping between H_4O_2 and H_5O_2^+ , or by a ‘vehicle’ mechanism in which the hydrogens and oxygens move together as H_3O^+ , is a matter of debate.

The spectral density function deduced by the method of temperature–frequency superposition from the temperature dependences of the ^1H T_1 , $T_{1\rho}$, and T_2 was found to be consistent with theoretical models of two-dimensional diffusion.²² Analysis of the ^{31}P solid echo shapes indicated that all the hydrogens are rapidly exchanging. The ^2H spectrum (see also *Deuterium NMR in Solids*) has an axially symmetric lineshape. This also is consistent with fast, discrete jumps of deuterium between the sites located by neutron diffraction studies. The conclusions of PFG studies are in good agreement with the NSR studies.

5.2 Amorphous FICs

5.2.1 Polymer Electrolytes

These are formed by dissolving ionic salts, e.g. LiClO_4 , in polymers that contain polar groups, e.g. polyethers such as poly(ethylene oxide) (PEO).²³ The proposal that thin, flexible films of these materials could be used as battery electrolytes excited considerable interest (*Conducting Polymers*). Because of complications associated with cross relaxation-effects, the interpretation of NSR data is not easy, but PFG methods have been used successfully for rubbery phases. Diffusion coefficients of ^7Li and ^{19}F have been measured for $(\text{PEO})_8\text{LiCF}_3\text{SO}_3$, showing that the anion CF_3SO_3^- is surprisingly more mobile than the lithium ion.

5.2.2 Glassy FICs

Fast ion conducting glasses typically consist of an oxide network former, e.g. B_2O_3 , GeO_2 , SiO_2 , or P_2O_5 , which together with a network modifier, e.g. Ag_2O_3 or Li_2O , can dissolve a salt, such as AgI or LiI , as a dopant. Highly conducting glasses are also based on sulfide and selenide

Figure 4 Spin–lattice relaxation $1/T_1$ of ^7Li in $(\text{Li}_2\text{S})_{0.56}(\text{SiS}_2)_{0.44}$ as a function of reciprocal temperature. Fits using equation (13) with a Gaussian distribution of activation energies are shown as solid lines. (Reproduced by permission of the American Institute of Physics from Svare et al.²⁴)

network formers, e.g. SiS_2 and GeSe_2 (see also *Quadrupolar Nuclei in Glasses*).⁷

The non-BPP $1/T_1$ vs. $1/T$ curves for ^7Li (Figure 4) and the anomalous conductivity, $\sigma(\omega, T)$, for the glassy FIC $(\text{Li}_2\text{S})_{0.56}(\text{SiS}_2)_{0.44}$ were fitted most satisfactorily by a model of lithium ion motion using a Gaussian distribution of activation energies [equation (13)].²⁴ The measured values of τ_c from the two effects differ by two orders of magnitude and this difference is explained by percolation around the high barriers in the distribution. The differences between the correlation function derived from NMR and that from conductivity is intimately related to the local versus macroscopic character of the two correlation functions, which becomes important in the presence of disorder. The data can also be fitted to stretched-exponential (KWW) correlation functions [equation (14)]. Neither the ‘diffusion-controlled relaxation’ model nor the ‘jump relaxation’ model, which incorporate ionic correlations to explain non-Debye-like relaxation in conductivity and non-BPP-like NMR relaxation, predict the differences between the correlation functions for T_1 and σ found experimentally.

1 INTRODUCTION TO NMR OF HYDROGEN–METAL SYSTEMS

The exposure of hydrogen to metals often produces significant changes in the physical properties of those metals. The absorption of hydrogen into interstitial lattice sites between metal atoms causes metallic materials to expand their volume, changes the crystal structure, and may change the electronic structure or electrical character of the material. Unable to withstand the strain, some metals fracture into powder, sometimes a useful method of producing powder of ductile metals, but at other times a possibly disastrous result as in the case of hydrogen embrittlement of steels. All the materials included in hydrogen–metal systems (HMSs) are occasionally incorrectly referred to as metal hydrides. As we will see below, metal hydrides do make up the majority of materials in HMSs. Metal hydrides can be either covalent, ionic, or metallic¹ in nature. We will confine our attention to metallic hydride materials.

One of the earliest NMR studies of hydrogen in metals was done some 40 years ago by R. E. Norberg,² who applied hydrogen to the palladium metal wires which made up the rf coil of his NMR probe. Linewidth, Knight shift, and relaxation times of the hydrogen in the rf skin depth of the palladium wires were studied by continuous wave and spin echo techniques.

Some of the most basic NMR studies of HMSs have been the investigation of the underlying physical principles governing hydrogen location and motion at the atomic or ‘microscopic’ level. Long-range hopping or diffusion of hydrogen is currently understood in terms of thermally activated, over the barrier hopping between interstitial lattice sites, which will be discussed, in part, below. Pulse magnetic field gradient NMR to measure hydrogen (and other atomic) diffusivities is discussed elsewhere (see *Diffusion in Solids*). Attempts to characterize tunneling of hydrogen at low temperatures between interstitial vacancies in metals at low temperatures by NMR will be discussed briefly here.

Although NMR is a powerful tool for observing hydrogen interactions in HMSs, interpretation of NMR data cannot be

done properly without other knowledge of the materials. Crystal structure and phase diagram results from X-ray, neutron diffraction,³ and detailed magnetic information from susceptibility measurements are often crucial to the interpretation of NMR results of HMS.

Many of the applied NMR studies of hydrogen, deuterium, and tritium in HMSs have been undertaken to determine the location and motions of hydrogen within the metallic materials in efforts to characterize and improve the hydrogen–metal materials for applications such as purification of hydrogen, hydrogen isotope separation, and hydrogen storage for fuel or energy storage (batteries); or closed cycle, metal hydride refrigerators for remote or applications to vehicles in space.⁴

HMSs include elemental metals, MH_x , with small concentrations of hydrogen, e.g. $x < 0.01$, dissolved in the host material with hydrogen located in interstitial vacancies without significant change in the crystal structure of the metal host, M . These materials are referred to as hydrogen (metal) solid solution (α) phases. The solubility of hydrogen in metal solid solutions often diminishes rapidly with decreasing temperature, forming metal hydride precipitates at lower temperatures. High hydrogen concentrations, $x = H/M$, often extend to $x = 3$ or 4 for metal hydrides, e.g. LaH_3 , SnH_4 , and PbH_4 , where the crystal structure of the hydride (β or γ) phase, e.g. face centered cubic (fcc) (or CaF_2 structure) for YH_2 , is usually quite different from the parent metal, e.g. hexagonal close packed (hcp) for Y , and the density of the metal hydride typically is less than the parent metal density. Intermediate hydrogen concentration samples may be mixed hydrogen–metal solid solution α and metal hydride β phases. The observed NMR spectra and nuclear spin–lattice, R_1 , and spin–spin, R_2 , relaxation rates as functions of temperature may give evidence of the mixed phases (see *Phase Transitions and Critical Phenomena in Solids*).

HMSs include hydrogen solid solutions of elemental metals, binary metal alloys, and intermetallic compounds, and also hydrides of metals, alloys, and intermetallic compounds. In addition, metallic halide compounds⁵ and metal sulfides⁶ adsorb hydrogen to significant degrees and should be included in HMSs. Some alloys and intermetallic compounds do not survive the hydriding process, but will disproportionate into hydrides of one or more of the metals and other compounds. In these cases, the hydride of the constituent metal is more stable than the hydride of the parent material.

Most NMR hydrogen–metal studies are made with samples sealed in quartz tubes to prevent loss of hydrogen upon heating the samples and to prevent oxidation or other contamination. Generally, the metallic nature of the materials requires powdered samples (particle size $\leq 100 \mu m$) to permit the B_1 rf magnetic field to penetrate the metallic particle’s ‘rf skin depth’ uniformly. The spaces between powder particles contain hydrogen gas molecules which represent a characteristic hydrogen over pressure of the particles typical for that material, nominal hydrogen concentration, and sample temperature. The hydrogen gas molecules between particles are in constant exchange with the hydrogen atoms or ions within the metallic particles. The hydrogen exchange rate is often quite low for room temperature, but may be many orders of magnitude greater for $T > 700 K$.

The density of the hydrogen inside some hydrogen storage materials, e.g. $LaNi_5H_6$, is greater than the hydrogen density in liquid hydrogen by a factor of two or three. Generally, the

hydrogen density in the metallic powders is many orders of magnitude greater than the density of gas molecules between powder particles. Thus, the observed hydrogen spectrum is typically the spectrum of the hydrogen in the metal only. Recently, anomalously high proton spin–lattice relaxation rates, R_1 , observed for $T > 700$ K within the metal particles⁷ have been understood in terms of exchange between bulk hydrogen atoms in the metallic powder and the much faster relaxing hydrogen gas molecules between the metallic powder particles⁸ (see *Hydrogen Molecules*).

2 HYDROGEN MOTION IN METALS DETECTED BY NMR

The early measurements of Norberg² demonstrated the motion of hydrogen in palladium. HMSs have been studied by NMR beginning with wideline CW methods measuring rigid lattice or low temperature linewidths and lineshapes. The low temperature or rigid lattice hydrogen linewidth originates from the magnetic interactions of the nuclear dipoles in the solid HMSs. Narrowing of the spectral lines with increasing temperatures gave clear evidence of hydrogen motion or hopping into interstitial vacancies within the solid.⁹ This rapid hopping of hydrogen results in a simple averaging of the local magnetic field B_L or the distribution of magnetic fields ‘seen’ by the hopping proton magnetic dipole moment. These motional narrowing studies yielded activation E_a energies of diffusion and moderately precise estimates of hydrogen jump frequencies, $\nu_j(T)$, or alternately, of hydrogen ‘dwell times’ or mean residence time, $\tau_D(T) = 1/\nu_j(T)$, and hydrogen correlation times, $\tau_c(T)$. With increasing T , when the average hydrogen jump frequencies exceeded the rigid lattice linewidth, the observed spectral lines narrowed. The temperature range for line-narrowing measurements was generally less than 100 K; Figure 1 from Schreiber and Cotts¹⁰ shows multiple line-narrowing graphs of LaH_{2+x} against

temperature. Lanthanum hydride shows the unusual ability to absorb hydrogen between compositions LaH_2 and LaH_3 , maintains an fcc structure, and with each additional hydrogen, every hydrogen atom jumps more rapidly. In most HMSs, with increasing temperature, the average hydrogen jump frequency can easily exceed the proton resonance frequency.

The proton linewidths versus temperature¹¹ in zirconium chloride hemihydride ($\text{ZrClH}_{0.5}$) and zirconium chloride monohydride (ZrClH) are shown in Figure 2. This transition metal halide structure consists of two zirconium metal layers sandwiched between two chlorine layers. Hydrogen is known to reside in interstitial tetrahedral sites between the two zirconium metal layers. In addition, the crystal structures for the hemi- and monohydrides are known to be slightly different, due to the presence of the hydrogen in the material.¹²

Indirect evidence of hydrogen (deuterium) hopping was also observed on studying the ^{93}Nb electric quadrupole perturbed, NMR satellite line narrowing in $\text{NbH}_{0.73}$ and $\text{NbD}_{0.82}$ with increasing temperature.¹³ Figure 3 shows the narrowing of the inhomogeneously broadened ^{93}Nb NMR satellite linewidth. This narrowing can be understood in terms of reducing the randomness (inhomogeneity) of the average value at the niobium ion sites due to the increased rapidity of the hopping motion of the hydrogen (deuterium) ions with temperature and their associated electrical charges in the vicinity of the niobium ion sites. The reduced average EFG at the ^{93}Nb site yielded a narrower NMR satellite linewidth. Thus, the stationary niobium NMR showed evidence of the mobile hydrogen (deuteron) ions hopping.

3 DYNAMIC STUDIES OF HYDROGEN MOTION IN A METAL

The magnetic dipole interactions of hydrogen with other hydrogen magnetic moments, with the host metal nuclear

Figure 1 Proton linewidths ($1\text{G} = 10^{-4}\text{ T}$) plotted against T for different x values. (Reproduced by permission of the American Physical Society from Schreiber and Cotts¹⁰)

Figure 2 Temperature dependence of the proton linewidth in the two hydride phases of ZrCl, measured at nominal resonance frequency of 26 MHz. (Reproduced by permission of Elsevier Science Publishers B.V. from Hwang et al.¹¹)

moments, paramagnetic impurity moments, and with conduction electron magnetic moments generally govern the flow of spin energy within HMSs. Cross relaxation of protons and host metal nuclei having large nuclear electric quadrupole interactions has been observed. Also, as shown below, the hopping deuteron can be relaxed by interactions of its electric quadrupole moment with fluctuating EFGs within the material.

The observed hydrogen spin–lattice relaxation rate $R_1(\omega, T)$ varies greatly with temperature in HMSs, and is often the sum of several independent $R_1(T)$ rates, each due to separate physical relaxation mechanisms active in the material. Fortunately, these several R_1 rates have different resonance frequency and/or temperature dependences. With this fact in mind, we shall see how one can separate these spin–lattice relaxation mechanisms and thereby begin to characterize the materials.

The observed hydrogen spin–lattice relaxation rate (HSLR) R_1 , in general, may be the sum of several of the following rates:¹⁴

$$R_1 = R_{1d} + R_{1e} + R_{1p} + R_{1CR} \quad (1)$$

where R_{1d} is the magnetic dipole–dipole relaxation of the hydrogen due to other hopping hydrogen. Bloembergen, Purcell and Pound¹⁵ (BPP) were first to suggest the form of relaxation

$$R_{1d} = \frac{1}{T_{1d}} = M_2(T)J(\omega_0, T) \quad (2)$$

where M_2 is a mean-square fluctuating field most commonly thought to be related to the magnetic dipole–dipole interaction of the hydrogen with other magnetic moments. However, in the case of the deuteron, this formalism can also be

Figure 3 Wide line absorption derivative spectra of ^{93}Nb for 300 and 386 K. At 386 K hydrogen jumping rates are sufficiently fast to produce a spatial average of the electric field gradient at the Nb metal sites which narrows the spectra. (Reproduced by permission of Elsevier Science, Inc., from Hwang et al.¹³)

expressed in terms of the fluctuations of the EFG about the deuteron electric quadrupole moment.¹⁶ In this case, R_{1d} is then written R_{1q} (q denoting quadrupolar relaxation). ω_0 is the spin precession frequency in angular frequency units. $J(\omega_0)$ is the power spectrum or spectral density function of the fluctuation magnetic fields (or fluctuating EFGs) within the sample. The simplest form of $J(\omega)$ is the Lorentzian

$$J(\omega) = \frac{\tau_c}{1 + \omega^2\tau_c^2} \quad (3)$$

where τ_c is the correlation time and is strongly temperature dependent. Often τ_c varies exponentially with temperature, where $\tau_c = \tau_0 \exp(-E_a/kT)$ and where $1/\tau_0$ is thought to be the attempt frequency of hydrogen jumping or the high temperature ‘rattling’ frequency of hydrogen within the interstitial site.

Equation (2) is often written with an additional Lorentzian term, including dipolar interaction terms at 2ω , as

$$R_{1d} = M_2(T) \left(\frac{\tau_c}{1 + \omega^2\tau_c^2} + \frac{4\tau_c}{1 + (4\omega^2\tau_c^2)} \right) \quad (4)$$

This simple description includes no details of the hydrogen interactions with metal nuclear moments or structure considerations of the HMS. It also ignores any orientation dependence of the crystal (sample) with the magnetic field $\mathbf{B}_0$ direction. Nonetheless, this BPP description is quite a good characterization of the hydrogen relaxation in many simple HMSs.

In a detailed description of hydrogen relaxation anisotropy in single crystal HMSs, Hoke et al.¹⁷ gave the relaxation rate

of protons in an hcp single crystal of $\text{ScH}_{0.25}$ as

$$R_1 = \left(\frac{\mu_0}{4\pi}\right)^2 \gamma_H^2 \gamma_S^2 \left(\frac{h}{2\pi}\right)^2 S(S+1) \left(\frac{1}{12} J^{(0)}(\omega_H - \omega_S) + \frac{3}{2} J^{(1)}(\omega_H) + \frac{3}{4} J^{(2)}(\omega_H + \omega_S)\right) \quad (5)$$

following Abragam¹⁸ where γ_H and γ_S are the gyromagnetic ratios of the hydrogen and metal, S is the spin (in this case, ^{45}Sc $S = \frac{7}{2}$), and $J^{(q)}(\omega)$ are spectral density functions which depend on the diffusion model chosen and on the orientation of the crystal in the magnetic field. Within the three spectral density functions $J^{(0)}$, $J^{(1)}$, and $J^{(2)}$ the frequencies $\omega_H - \omega_S$, ω_H , and $\omega_H + \omega_S$ are the difference between hydrogen and metal frequencies, the hydrogen frequency, and the sum of hydrogen and metal frequencies, respectively.

Interestingly, the anisotropy in R_1 originates in the anisotropy of $J^{(q)}(\omega)$, written by Sholl¹⁹ as

$$J_{qq'} = \sum_{\alpha, \beta} \frac{Y_{2q}(\Omega_\alpha)}{r_\beta^3} \frac{Y_{2q'}(\Omega_\beta)}{r_\beta^3} P(r_\alpha, r_\beta, \omega) \quad (6)$$

where Y_{2q} are spherical harmonics, r_α is the distance between the proton and metal spin at time zero, and r_β is the distance between the proton and metal spin at time t . $P(r_\alpha, r_\beta)$ is the Fourier transform of the probability function for the diffusion model chosen.¹⁷

The conduction electron moments in the HMS relax the hydrogen moment through a contact hyperfine interaction the same as is associated with the Knight shift.^{18,20} The relaxation rate R_{1e} is proportional to the temperature and the square of the Knight shift (see Section 4 for a simple description of the Knight shift) and the square of the density of unpaired electronic (moment) states at the Fermi energy $N(E_F)$. Generally, the better the conductivity of the metallic material the greater the electronic relaxation rate R_{1e} :

$$R_{1e} = \frac{1}{T_{1e}} \propto N^2(E_F) T \quad (7)$$

For a simple metallic material, combining the Knight shift with relaxation rate,

$$T_{1e} T K^2 = \frac{T}{R_{1e}} K^2 = \frac{h/2\pi \gamma_e^2}{4\pi k \gamma_n^2} \quad (8)$$

where γ_e and γ_n are the electron and nuclear (hydrogen) gyromagnetic ratios. This equation is known as the Korringa or Heitler-Teller-Korringa (HTK) relation,²¹ where the Knight shift and R_{1e}/T are theoretically constant in temperature and R_{1e}/T or $1/T_{1e}T$ is often used to characterize the electronic relaxation in HMSs.

Unwanted paramagnetic ion concentrations, ignored in several NMR studies of HMSs, have shown unusual, anomalous relaxation rates and 'extra features' in the measured HSLR which have been attributed to a fictitious complex or additional diffusion mechanism. Phua et al.²² showed that many such unusual or extra relaxation mechanisms were most likely due to the existence of residual paramagnetic impurities (dirt) in the host metals present at the time of the formation of the HMS. That study showed, generally, that the extra spin-lattice

Figure 4 Proton spin-lattice relaxation time T_1 vs. $1000/T$ in YH_2 vs. Gd impurity concentration. (Reproduced by permission of American Physical Society from Phua et al.²²)

relaxation rates, R_{1p} , were linearly proportional to the concentration of paramagnetic impurities present. In addition, extra minima in $\log(T_1)$ versus $1/T$ were a direct result of the impurity relaxation; see Figure 4 for evidence of the suppression of $\log(T_1)$ versus $1/T$ and 'extra minima'. The paramagnetic moments produce a relaxation rate R_{1p} in HMS and can relax hydrogen by spin diffusion at low temperature in the low hydrogen diffusion regime. At higher temperatures, in the fast diffusion regime, hydrogens approach the stationary paramagnetic ions by rapid hopping within the sample and are relaxed via direct dipolar interactions with the paramagnetic impurity ions.

The cross relaxation of the proton, R_{1cr} , with certain host metal nuclei which have large electric quadrupole moments and subsequently large quadrupole interactions was recognized for protons in HMS at low temperatures (see Figure 5) where hydrogen hopping rates are slow. The strong nuclear electric quadrupole interactions of the metal nuclei, e.g. ^{175}Lu in $\text{LuH}_{0.20}$ ²³ and ^{181}Ta in Ta_2H ²⁴ are many tens of megahertz in extent (width) and are only perturbed by the static magnetic field B_0 required for proton resonance. Although the ^{93}Nb quadrupole moment and interaction in $\text{V}_x\text{Nb}_{1-x}\text{H}_y$, for example, is weaker than ^{181}Ta in Ta_2H and ^{175}Lu in $\text{LuH}_{0.20}$, for frequencies $f_{\text{max}} < 24$ MHz, protons also cross relax to ^{93}Nb . When the proton resonance frequency matches one of the many spectral features of the metal NQR, spin polarization energy is transferred from the proton to the metal nucleus. The spin polarization energy is taken from the metal nucleus by the conduction electron interaction to the lattice because the contact hyperfine interaction is much stronger and thus faster (or higher rate) for the metal nucleus than for the proton. Figure 6 shows the proton cross relaxation to ^{181}Ta in $\text{TaH}_{0.32}$ as a function of proton resonance frequencies²⁴ (for a series of magnetic field values) while at $T = 130$ K. The calculation of the cross relaxation as a function of proton frequencies is described by Lichty et al.²⁴

Figure 5 Proton spin-lattice relaxation rates R_1 vs. $1000/T$ in LuH_x at 12, 40 and 65 MHz. Cross relaxation between the protons and the ^{175}Lu nuclear electric quadrupole broadened NMR lines can be seen at low temperatures in the loss of temperature dependence for $T \leq 400$ K. (Reproduced by permission of R. Oldenbourg Verlag from Torgeson et al.²³)

Figure 7 shows the total spin-lattice relaxation rate versus reciprocal temperature in schematic form, typical of many HMSs with the several component relaxation rates identified.

4 DEUTERON LINESHAPE FOR COMBINED ELECTRIC QUADRUPOLE AND KNIGHT SHIFTS

The Knight shift of hydrogen results from a small magnetic field at the hydrogen nucleus in an HMS from the conduction electron wave function $|\psi(0)|^2 \neq 0$ for the s electron character of the conduction electrons. This is often called the ‘contact hyperfine interaction’ or Fermi contact term. The application of the B_0 field causes a small paramagnetic polarization of the conduction electrons, called the Pauli paramagnetism, where $M_s = \chi_s B_0$ and χ_s is the Pauli spin susceptibility. χ_s can be related to the density $N(E_F)$ of unpaired conduction electron states at the top of the conduction electron distribution or at the Fermi energy via the Pauli susceptibility $\chi_s = \frac{1}{2}(\gamma_e h)^2 N(E_F)$. The Knight shift can be written simply as $K \approx \chi_s |\psi(0)|^2 / N$. The Knight shift causes a fractional change in the proton (deuteron) gyromagnetic ratio, that is, a small shift in position of the hydrogen resonance ΔH for fixed frequency or $\Delta \nu$ for

Figure 6 Proton cross-relaxation data (●) to ^{181}Ta nuclear electric quadrupole broadened NMR lines in $\text{TaH}_{0.32}$ as a function of a series of proton resonance frequencies at 130 K. See Lichty et al.²⁴ for details of the theoretical calculations and the three curves presented. The analysis yielded a ^{181}Ta nuclear electric quadrupole frequency $\nu_Q = 43$ MHz and electric field gradient asymmetry parameter $\eta = 0.35$. (Reproduced by permission of American Physical Society)

fixed field measurements

$$K = \frac{\Delta H}{H} = \frac{H_R - H_M}{H_R} = \frac{\Delta \nu}{\nu} = \frac{\nu_M - \nu_R}{\nu_R} \quad (9)$$

where subscript M refers to the metal field or frequency and R refers to the reference (solution or free ion) field or frequency. These fractional shifts are generally independent of the field or frequency.

Knight shifts of hydrogen in HMSs are generally quite small in magnitude compared with Knight shift values of metals, and often smaller in field shift magnitude ΔH than the dipolar broadened width or the B_L local magnetic field in the solid. However, the magnetic moment of the deuteron is smaller than the proton by a factor of 3.3, and effects of local magnetic fields are correspondingly smaller than for the proton. Figure 8 shows the combined effects of ^2D nuclear electric quadrupole interaction and Knight shifts²⁵ in a sample of $\text{NbD}_{0.76}$. The general subject of combined nuclear electric quadrupole interactions and Knight shift interactions in metals was first presented by Jones et al.²⁶ Since the ^2D spin $I = 1$, there are $2I + 1$ or 3 levels and two transitions and no ‘central line’. These two transitions for spin $I = 1$ are commonly referred to as the Pake doublet,²⁷ following the terminology established by George Pake in 1948 for the interaction of two coupled protons of combined spin $I = 1$ in the water of hydration in gypsum.

$\text{NbD}_{0.76}$ is orthorhombic in structure and thus the EFG and the Knight shifts must be described by tensors. The principal

Figure 7 Generalized proton spin–lattice relaxation rate R_1 contributions vs $1000/T$. These relaxation rates are: conduction electron, R_{1e} ; long range diffusion/dipole–dipole, R_{1d} ; paramagnetic impurity ion, R_{1p} ; and cross-relaxation to quadrupole (metal) nucleus, R_{1cr} . The relative weighting of these mechanisms depends on the purity and physical details of the HMS sample studied

axis system of the EFG has three separate components V_{xx} , V_{yy} , and V_{zz} , the second derivatives of the crystalline potential with respect to the coordinates x , y , and z . Note that $\nabla^2 V = V_{xx} + V_{yy} + V_{zz} = 0$ is Laplace's (electrical) equation. In the principal axis system, $|V_{xx}| < |V_{yy}| < |V_{zz}|$. The EFG asymmetry parameter for $\text{NbD}_{0.76}$ is $\eta = (V_{xx} - V_{yy})/V_{zz} = 0.11$. If η were equal to 0, then $V_{xx} = V_{yy}$ would require axial symmetry, i.e. at least three-fold rotational symmetry about the z axis. $\eta \neq 0$ implies the $\Delta m = \pm 1$ transitions $-1 \leftrightarrow 0$ and $0 \leftrightarrow +1$ in combination with the K_x , K_y , and K_z Knight shift components will produce different frequency dependences for the two transitions or ^2D 'powder' lineshapes.²⁵ The width of the pattern essentially measures the strength of the deuteron electric quadrupole interaction described by the lowest pure quadrupole frequency $\nu_Q = 3eQV_{zz}/2h = 49.3 \text{ kHz}$, where eQ is the deuteron quadrupole moment, V_{zz} is the principal component of the EFG tensor and h is Planck's constant. Incidentally, $\nu_Q = 3eQV_{zz}/[2I(2I-1)h]$ is the best measure of the strength of the quadrupole interaction relative to the strength of the NMR interaction characterized by ν_0 , the Larmor frequency.²⁸

For powdered metal hydrides with less than cubic crystal symmetry, the single grain particles' major symmetry axes will simply point in random directions in space. However, with an applied magnetic field switched on, the majority of particles' major symmetry axes will be nearly perpendicular to the field direction and a small minority of crystal symmetry directions will point along the field direction. This produces the well

Figure 8 (a) Deuteron absorption curve vs. frequency for $\text{NbD}_{0.56}$, (b) derivative of observed deuteron absorption curve, and (c) calculated deuteron absorption derivative curve lineshape. (Reproduced by permission of Academic Press from Torgeson et al.²⁵)

known $\sin \theta$ dependence of the distribution of powder particle orientations with respect to the magnetic field direction. As pointed out by Jones et al.²⁶ the major peaks of the absorption spectrum are due to 'singularities' at the perpendicular ($\theta = 90^\circ$) powder grains, and the smaller 'steps' at the extremes of the spectrum are due to those particle crystallites nearly parallel ($\theta = 0^\circ$) to the magnetic field.

The deuteron Knight shift, as for all hydrogen Knight shifts, originates from the contact hyperfine interaction of the conduction electrons at the deuteron (hydrogen) nucleus. In the HMS, the conduction electrons are attracted or 'cored' to the hydrogens in the same way conduction electrons are attracted to the metal nuclei. This, of course, makes the conduction electron wave functions more complex than in the pure metal, alloy, or intermetallic compound. The presence of

the hydrogen may actually change the electronic character of the HMS by changing the conduction electron wave functions and by the hydrogen donating an electron to the conduction band when hydrogen is absorbed, which may greatly modify the electronic band structure of the HMS.

The effect of the Knight shifts on the observed lineshape is simply a small displacement of the resonance position due to an additional magnetic field at the nucleus from the contact hyperfine interaction. For a non-cubic metal or HMS, the magnitude of the shift of the resonance is dependent upon orientation of the crystalline axes of the grain with respect to the field direction. Figure 8 (a) shows the observed absorption curve, (b) a derivative of the observed absorption and (c) a calculated absorption derivative with appropriate Knight shift and EFG components included. Absorption derivative lineshapes actually show more subtle lineshape features than do the absorption curves. Absorption derivatives lineshapes were commonly recorded in field or frequency scanned CW wideline studies in past years because of the use of lock-in amplifiers and small amplitude magnetic field or frequency modulation to record spectra.

5 LOW TEMPERATURE LOCAL HYDROGEN MOTION AND HYDROGEN TUNNELING IN HMSs

Scandium, yttrium, and lutetium plus other rare earth hcp metals provide a nearly unique opportunity to observe hydrogen dissolved in metals and measure hydrogen motions in metals at temperatures below 150 K. Unlike many transition metals, scandium, yttrium, and lutetium can maintain up to 30 at% hydrogen in solution without precipitating any of the hydride phase²⁹ down to 4 K or without transforming to another crystal structure.

Lichty et al.³⁰ measured proton R_1 s in $\text{ScH}_{0.27}$ ($\text{H}_{0.18}$) and found both an electronic relaxation R_{1e} and a weak low temperature motional relaxation peak R_{1L} near 60 K (105 K). That peak moved with the proton resonance frequency in a manner similar to the movement of R_{1d} , the over the barrier hopping, long range diffusion relaxation rate peak at much higher temperatures. In Figure 9 we see these low temperature data for two proton frequencies. The R_{1L} motional relaxation peak is superimposed on the R_{1e} electronic relaxation, which is linear in temperature T ($R_{1L} = R_1 - R_{1e}$; R_{1L} will be discussed below).

The location of hydrogen (deuterons) in the scandium hcp lattice was studied by neutron scattering.²⁹ Deuterons were found to prefer to form pairs with a scandium atom between. From these neutron scattering studies, models of hydrogen ordering in chains of paired hydrogens in scandium were proposed.

The pairing of hydrogen with a scandium metal between is an interesting and unusual ordering. However, not all hydrogens are paired with a metal between. Some of the hydrogens are unpaired and thus occupy vacant tetrahedral (T) sites in a random or inhomogeneous manner. The random occupation of hydrogen in metal-solid solutions has been referred to by Barnes¹⁴ as a proton glass. The result of an inhomogeneous hydrogen occupation can be seen in the proton spin-lattice relaxation rate data and will be explained below.

The scandium hcp lattice has two adjacent, closely spaced interstitial T sites along the c axis where hydrogen is known²⁹

Figure 9 Proton spin-lattice relaxation rate (R_1) in $\text{ScH}_{0.27}$ as a function of temperature at 24 and 62 MHz. Proton R_1 in $\text{YH}_{0.18}$ at 24 MHz ($\bullet$) shows a weak peak at ~ 105 K. The peak heights are due to the relaxation of the proton's tunneling motion and proton dipole 'collisions' with fixed (^{45}Sc or ^{89}Y) metal nuclear magnetic moments. Note the ^{89}Y moment is $< 1/20$ of the ^{45}Sc moment. (Reproduced by permission of the American Physical Society from Lichty et al.³⁰)

to sit in one of the sites. These two sites are too closely spaced to permit two hydrogens to occupy both sites simultaneously.³¹ The local motion is understood to be one hydrogen moving between these two closely spaced T sites. Activation energies derived from a 'local over a small barrier' hopping model were found to be $E_a \approx 50$ meV, much smaller than the nominal 500 meV activation energies typical of long-range hopping over a barrier found for activation energies in higher temperature hydrogen diffusion. Lichty et al.³⁰ were able to fit the proton spin-lattice relaxation rates versus $1000/T$ with two separate and quite different models for hydrogen hopping over an energy barrier. As can be seen from Figure 10, the data are not symmetrical about the peaks of the three relaxation curves. The slope of the three curves on the high temperature (low $1/T$ values) side of the peak is much greater than the low temperature (higher $1/T$ values) slopes. Symmetrical $\log R_1$ versus $1/T$ curves in HMSs is a signature of hydrogen hopping where there is one unique activation energy typifying a simple hopping process and/or a simple and often cubic solid. Symmetrical $\log R_1$ or $\log T_1$ vs $1/T$ curves are often referred to as BPP type behavior. The relaxation rate curves in Figure 10 show the signature of hydrogen motion in a disordered solid with a distribution of activation energies. This subject will be discussed at length below. Lichty et al.³⁰ were able to fit the data with two hopping models, one assuming a distribution of activation energies and a second model with a correlation

Figure 10 Proton spin-lattice relaxation rate in $\text{ScH}_{0.27}$ vs. $1000/T$ for proton resonance frequencies 12, 40, and 90 MHz fitted with a thermally activated over the barrier hopping model and a distribution of activation energies. function having a stretched exponential character. Localized hydrogen motion has also been found by Skripov et al.³² in TaV_2H_x in the temperature range 10–100 K.

Tunneling of hydrogen from one tetrahedral interstitial site to an adjacent empty T site at low temperature is an alternate mechanism rather than hydrogen thermally activated hopping over a low energy barrier. Svare et al.³³ suggested that the same proton spin-lattice relaxation data of Lichty et al.³⁰ in $\text{ScH}_{0.27}$ could also be described by hydrogen tunneling between adjacent T sites in the Sc hexagonal close packed lattice. The potential wells for the two sites were thought to have sinusoidal curvature near the bottoms. The two wells of the adjacent T sites were also thought to have different minimum energies, that is, the wells were asymmetric. In fact, Svare et al.³³ suggested the asymmetry, A , for the hydrogen-scandium metal solid solution would have a distribution of minimum energy difference values typical of an inhomogeneous hydrogen solid solution or proton glass. With increasing temperature, the tunneling model must include a tunneling mechanism not appropriate (or yet thermally switched on) at lower temperature. Figure 11 shows the proton spin-lattice relaxation data of Lichty et al.³⁰ fit with this tunneling model. The data fit adequately this tunneling theory and support the proposition that hydrogen tunneling exists in scandium at low temperatures. Hydrogen tunneling in scandium was also found by Leisire et al.³⁴ in a resonant ultrasound spectroscopy (not an NMR technique) study of $\text{ScH}_{0.25}$ and $\text{ScD}_{0.18}$ employing small scandium single crystals.

6 SPIN-LATTICE RELAXATION IN AMORPHOUS HYDROGEN-METAL SYSTEMS

An amorphous metal alloy may be formed by extremely rapid cooling of the molten metal alloy. Such materials are often referred to as metallic glasses. An amorphous alloy is a

Figure 11 Low temperature proton spin-lattice relaxation rates $R_{\text{IL}} \equiv T_{\text{IL}}^{-1}$ versus reciprocal temperature in two hcp scandium-hydrogen solid solution compositions. (a) $\text{ScH}_{0.27}$ and (b) $\text{ScH}_{0.11}$ at 24 MHz (+), 40 MHz (x), and 90 MHz (•), respectively. The curves represent the fits of the tunneling model with a distribution of asymmetric energy well minima for hydrogen tunneling between adjacent tetrahedrally coordinated interstitial (T) sites. Data are from Lichty et al.³⁰ and tunneling model can be found in Svare et al.³³

disordered metal and is without long range topological order. There may be short range or compositional order in amorphous alloys. These amorphous materials are then hydrided by more or less conventional means, but care must be taken not to heat the material high enough to 'recrystallize' the amorphous sample. This may be somewhat difficult as the absorption of hydrogen by metals is generally an exothermic reaction.

Bowman³⁵ points out that metallic alloy glasses must contain one of certain metals, i.e. titanium, zirconium, hafnium, palladium, or a rare earth metal, for the glass to be able to hold hydrogen, $\text{H}/\text{M} > 0.1$, where M is the total metal content. Even with one of these metals in the alloy, an alloy glass may not be formed upon quenching.

Hydrides of metallic glasses generally have quite different hydrogen motions, with lower hydrogen diffusion activation energies and spin-lattice relaxation rates than do hydrides of the crystalline HMSs of similar composition as we shall see below. In the case of crystalline and amorphous Zr_2PdH_x , Bowman et al.³⁶ point out the $\log T_1$ versus $1000/T$ plots for $\text{Zr}_2\text{PdH}_{2.90}$ and amorphous $\text{a-Zr}_2\text{PdH}_{2.90}$ are noticeably

Figure 12 Proton spin-lattice relaxation times vs. $1000/T$ for crystalline $\text{Zr}_2\text{PdH}_{1.84}$ and $\text{Zr}_2\text{PdH}_{2.90}$ at 40 MHz and amorphous $\text{Zr}_2\text{PdH}_{2.90}$ at 34.5 MHz, and proton relaxation times for crystalline and amorphous $\text{Zr}_2\text{PdH}_{2.90}$ vs. $1000/T$. The latter curve shows hydrogen diffusion at lower temperatures and with lower activation energy (slope of T_1 vs. $1000/T$ curve) than the crystalline $\text{Zr}_2\text{PdH}_{2.90}$. (Reproduced by permission of R. Oldenbourg Verlag from Bowman et al.³⁶)

different. The crystalline and amorphous curves have minima at different temperatures and have different slopes or diffusion activation energies. Generally, the amorphous samples display more rapid hydrogen diffusion at lower temperatures and have lower activation energies for diffusion than do the crystalline equivalents. This can be seen in Figure 12. A simplistic explanation of this effect may relate in part to the fact that the glassy HMSs have a somewhat lower density and have more 'open' paths for hydrogen to hop through than the crystalline equivalents. A more complete description of hydrogen motion must also include the differences in electronic character known to exist between the glassy and crystalline HMSs.

1 INTRODUCTION—NMR AND STRUCTURE OF METALS

The Knight shift refers to the relative shift K in NMR frequency for atoms in a metal (e.g. sodium) compared with the same atoms in a nonmetallic environment (e.g. sodium chloride). The observed shift reflects the local magnetic field produced at the sodium nucleus by the magnetization of the conduction electrons. The average local field in sodium augments the applied resonance field by approximately one part per 1000. In nonmetallic sodium chloride the local field is negligible in comparison.

Conduction electrons¹ in a metal are delocalized, meaning that no electron is uniquely associated with any particular atom more than another but all exist in eigenstates within an energy band, whose highest occupied state lies at an energy E_F , the Fermi energy. At lower energies the electron wave functions tend to be mainly s states, while at higher energies there are increasing admixtures of higher (p , d , ...) states. For s states the probability density at the nucleus ($R = 0$) is high, and since each electron carries a spin and magnetic moment μ_B , the contact interaction momentarily produces a local magnetic field at the nuclei, as the electron moves through the lattice.

The local hyperfine field in atomic sodium is approximately 39 T. This is an atomic property, independent of external fields. The average contact hyperfine field in a metal is zero, in zero applied field, because the nucleus is exposed to equal numbers of spin-up and spin-down electrons. In an externally applied magnetic field the conduction electron system acquires a magnetization proportional to the magnetic susceptibility of the conduction electron system. The appropriate susceptibility χ_p is the temperature independent Pauli paramagnetism. Because the electron magnetic moments parallel to the applied field have the lower energies, the parallel orientation is more favorable than the antiparallel, and consequently the number of parallel moments is greater, hence the paramagnetism. The

fractional change in field, or observed resonance frequency, is²

$$K = \Delta B/B = \Delta\nu/\nu = (8\pi/3)\chi_p V_0 P_F \quad (1)$$

where χ_p is the Pauli susceptibility per unit volume, V_0 is the volume per atom in the metal, P_F is the average value of the s electron probability density at $R = 0$, B is the applied magnetic field, and ν is the observed resonance frequency. The average P_F is taken for electrons at the Fermi energy E_F . The local field of p electrons is usually 10% or less of the contact interaction, and produces small anisotropic shifts in noncubic metals (c.f. Section 2.3). The anisotropic effects vanish in cubic metals. In noncubic metals the effects are relatively small, but yield valuable information concerning electronic and crystal structures.

To summarize some typical parameters: the hyperfine field per electron in a free sodium atom is 39 T; the corresponding contact hyperfine field in metallic sodium is smaller, ~ 30 T, mainly because of p admixtures in the wave functions at the Fermi surface; the small Pauli susceptibility reflects the small number of unpaired spins; the average local field is 1.1×10^{-3} T for an applied field of 1 T; and equation (1) gives $K = 0.11\%$.

Values of K have been measured for most of the metallic elements, and recorded results range approximately from $K = 0.026\%$ (Li) to 2.7% (Hg). The measurement of K is a sensitive means for probing, noninvasively, electronic and geometric structures of metallic systems in solids and liquids, and has been of value in studying phase transitions in metals, alloys, intermetallic compounds, and superconductors.³

2 LATTICE STRUCTURE AND DYNAMICS

2.1 Effects of Pressure, Volume, and Temperature

It is evident from equation (1) that insofar as the parameters χ_p , V_0 , and P_F depend on pressure, volume, or temperature, K is affected by, and is a measure of, these variables. Compressing a specimen effectively changes the volume per atom and P_F , while heating affects the volume, the lattice dynamics, and electron-phonon interactions as well. Although the Pauli susceptibility is essentially independent of temperature, other contributions to the susceptibility are temperature dependent, and NMR shifts have corresponding temperature dependences (c.f. Sections 3.1 and 3.2).

In order to find the intrinsic temperature dependence, one can measure K versus T at constant P , and K versus V at constant T , also knowing the thermal expansion coefficient and compressibility. With so many variables, the end results are useful, but may not be as precise as one would wish. Bloembergen has pointed out⁴ that P_F is nonlinear with respect to volume, and χ_p depends on lattice vibration frequency via spin-lattice relaxation.

Recently, Götz and Winter⁵ have considered the volume dependence of K for the alkali metals lithium and sodium, for which many experimental data exist. They pointed out that the theoretical analysis requires the inclusion of orbital plus exchange and correlation terms (c.f. Sections 3.1 and 3.2). While they were able to arrive at good agreement with the experimental results for lithium, the result for sodium is less clear. The work serves to illustrate the fact that the theoretical problems are more elaborate than was believed at first.

2.2 Anisotropic Shift

For noncubic crystals K becomes a function of crystal orientation with respect to the applied field.⁶ We can perform and analyze NMR shift experiments in crystals with axial symmetry, for example, introducing the axial shift K_{ax} , which depends on hyperfine magnetic fields at the nucleus generated by p electrons. These fields are generally 10% or less of the contact hyperfine fields, but valuable structural information may be obtained.⁶

For crystals of axial symmetry, the anisotropic part of the NMR shift is a function of the angle θ between the principal symmetry axis and the applied magnetic field.

$$K_{\text{ax}} = q_F \chi_p (3 \cos^2 \theta - 1) \quad (2)$$

The shape of the p electron charge distribution and its dipole field at $R = 0$ are included in the function q_F in equation (2). For an axially symmetric crystal the total NMR shift is the sum of equations (1) and (2).

For a single crystal specimen the NMR appears at frequencies varying between extremes at $\theta = 0^\circ$ and 90° . A polycrystalline sample shows a broadened lineshape between the above extremes, with the largest intensity near $\theta = 90^\circ$, and the frequency of minimum intensity appears at higher frequency for positive q_F . For nonaxial symmetry, the corresponding extended analysis is straightforward.⁶ Experimental results are also interpreted in terms of crystal structure and electronic band structure (s-p admixture).

2.3 Quadrupole Coupling

An analysis similar to the above can be made for nuclei with the quadrupole moment Q in a noncubic environment. The first-order quadrupole interaction frequency is

$$\nu = e^2 q Q / h \quad (3)$$

where q is the local electric field gradient at the nucleus, which depends on crystal structure ($q = 0$ in cubic symmetry). For a first-order interaction in a specimen with nuclear $spin - \frac{3}{2}$ the spectrum consists of a pair of satellites astride the central NMR resonance and split by $\pm e^2 q Q / 4h$. More complete discussions, including second-order quadrupole effects, are available.⁶

3 ORBITAL AND CORE POLARIZATION SHIFTS, SPIN RELAXATION

3.1 Orbital Paramagnetism

Several other factors contribute to the total NMR shift in metals. Beyond the Pauli term in equation (1), there is the orbital (Van Vleck) paramagnetism, and also the core polarization by d electrons. Each of the above effects is associated with a respective magnetic susceptibility, and may be summed as follows:

$$\chi = \chi_p + \chi_v + \chi_d \quad (4)$$

The Pauli term χ_p predominates in light monovalent metals, while the second and third terms generally make large contributions in heavy and transition metals. The first two are nearly independent of temperature in the normal state. The last tends to be paramagnetic and temperature dependent for transition metals with narrow d bands and low Fermi temperatures.

The orbital paramagnetism χ_v is a second-order effect in solids analogous to the Van Vleck temperature independent paramagnetism in molecules.^{7,8} It arises because of the mixing of filled and unfilled orbitals in the same band. It appears that the contact term χ_p for vanadium is approximately cancelled by the negative χ_d term, and small compared with the orbital χ_v term.⁹ This conclusion is consistent with the fact that the NMR shift in vanadium is minimally affected by the transition to the superconducting state (the predominant orbital hyperfine field is not related to electron spin pairing—see Sections 3.2, 4.3, and 6.1).

The orbital susceptibility can be estimated⁸ in several ways, one of which can be expressed as

$$\chi_v \sim 2\mu_B^2 N / E \quad (5)$$

where N is the number of d electrons per unit volume, and E is the average energy separation of the mixed states.

3.2 Core Polarization

The third term in equation (4) represents the temperature dependent paramagnetic d states. Although the direct hyperfine interaction of d electrons is small, s electrons (either in a filled shell or in an s band) couple¹⁰ with the paramagnetic d electrons and produce hyperfine fields which can be comparable (or of opposite sign) to the direct s electron contact interaction. For example, in platinum the predominant contribution¹¹ to K derives from core polarization, which is calculated to be negative, resulting in a large observed negative shift, $K_{\text{Pt}} = -3.5\%$.

A recent band structure Green's function analysis¹² points out that equation (4) implies independence among the several terms, while in fact the terms are not strictly independent, and it is in principle necessary to include spin-orbit and exchange correlation effects in the calculations. It is also clear from their results and comparison of several calculations with equation (5) that the latter provides useful but imprecise estimates for susceptibilities and shifts. The theoretical results support the previous interpretations for the observed shifts in vanadium⁹ and platinum.¹¹

3.3 Diamagnetism of Conduction Electrons

In addition to the terms in equations (1) and (4), the contribution of the Landau diamagnetism by the conduction electrons is significant. When a magnetic field is applied to the conduction electron system, the levels split so that the average energy of the system increases, corresponding to a diamagnetism of one-third χ_p ,¹³ with a correction factor involving the electron effective mass:

$$\chi_L = -(\chi_p/3)(m/m^*)^2 \quad (6)$$

This χ_L term appears to be significant but relatively small in most metals, and is believed to be mainly responsible for the large negative $K = -1.25\%$ in solid bismuth, which is characterized by a very small effective mass. By contrast, liquid bismuth behaves more like an ordinary metal, since $K = +1.4\%$ in the liquid. A further interesting observation is the oscillation of K as a function of applied magnetic field, in analogy to the de Haas–van Alphen effect.

3.4 Korringa Relation

An important means of directly relating metallic properties to NMR experiments depends on the Korringa relation,⁴ which is based on the fact that the nuclear spin relaxation rate $1/T_1$ varies directly as temperature T and the square of the density of states $[N(E_F)]^2$ at the Fermi surface, while K is simply proportional to $N(E_F)$. In abbreviated form the Korringa relation is expressed

$$K^2 T_1 T \sim S \quad (7)$$

The Korringa product factor S on the right-hand side of equation (7) includes the magnetogyric ratios of the electron and nucleus. Equation (7) permits an independent evaluation of K in cases where χ is uncertain. The order of magnitude of S is generally unity when K is dominated by the contact interaction, as is true for the alkali and simple metals. For transition metals, where $S \gg 1$, equation (7) must be used with caution, noting also that the measured T_1 may include a contribution produced by fluctuating nuclear quadrupole interactions. The orbital paramagnetism χ_v depends on the average density of states over the conduction band and should not be included in a calculation involving equation (7), since χ_p and K depend simply on $N(E_F)$.

3.5 Overhauser Effect

The contact hyperfine interaction which produces the Knight shift, as well as relaxing the nuclear spins, acts reciprocally to produce a magnetic field on the conduction electrons because of the large nuclear polarization. This interaction produces a shift in the ESR, and a large enhancement of the NMR intensity, the Overhauser effect.¹⁴ The magnitude of the intensity enhancement is easily a factor of 10 or more. Under conditions of maximum NMR intensity enhancement, the ESR is saturated, and the frequency of the ESR is shifted (the Day shift).

4 STRUCTURES OF ALLOYS

4.1 Metallurgical Phases in Simple Binary Alloys

The classical treatment of alloys was based on thermodynamic analysis, crystal structures, and the average electron–atom ratios. Further local information is obtained by measurements of the Knight shift. Alloys of cadmium in silver include an α phase (face-centered cubic) with up to $\sim 40\%$ cadmium, followed by a mixed α and β phase (41–49%

cadmium), then a β phase (body-centered cubic) (49–51% cadmium), followed by the phases γ , ϵ , η (pure Cd). The mixed phases are characterized by two NMR lines with K values appropriate to the respective adjacent pure phases.^{6,15}

In the α phase of silver–cadmium alloy, K_{Cd} decreases linearly from 0.59 to 0.53% at the β phase boundary. The silver shift drops linearly from 0.52 to 0.46% in the α phase, as predicted,¹⁶ but was not observed at higher concentrations because of low signal strength.

Analysis of the local electronic structure, as seen by the solute atom in the alpha phase may proceed on the basis of equation (1), using χ_p (solvent), and P_F (solute, modified to include s–p character of the solvent).

The average electron density is reduced by long range charge density oscillations in space, which are induced by the perturbing solute atoms.¹⁶ The net result is a decreasing average charge density at solvent atoms with increasing solute concentration. Since the charge density oscillates with relative positions of solute and solvent atoms, the average reduction of the K shift is accompanied by a resonance line broadening.

4.2 Intermetallic Compounds

These are alloys with definite stoichiometries. Depending on the constituents and temperature, intermetallic compounds may be metallic conductors, semiconductors, or superconductors (c.f. Section 6). It was found⁹ that K for vanadium is strongly dependent on temperature in the superconducting intermetallic compound V_3Ga . Just above the transition temperature T_c the vanadium shift $K_V = +0.45\%$, changing to $+0.65\%$ for $T \ll T_c$. Correspondingly, the gallium shift K_{Ga} changes from -0.8 to -0.2% . In both cases the average hyperfine field becomes more positive as the negative core polarization shift decreases. These results raise a number of interesting questions, such as what are the charge density patterns of the band electrons.

4.3 Alloys with Dilute Magnetic Impurities

The scattering of conduction electrons by impurity atoms is considered in Sections 4.1 and 5.3. Long range spatial charge oscillations and indirect spin couplings¹⁷ between distant electrons and nuclei result in long-range variations in local fields, and polarizations which couple with host atoms as well as other impurities. NMR shifts and line broadenings are observed, in addition to resolved satellites for the NMR resonance lines.¹⁸

4.4 Muon Spin Resonance

Just as the conduction electrons probe the atom cores, the muon spin rotations, prior to their decay, provide signals measuring the local magnetic fields near the decay sites.¹⁹ Knight shifts of from 10 to 100 ppm are observed for μ^+ at frequencies of a few megahertz in fields of a few kilogauss. Muon spin resonance techniques have the advantages of fast timescales and no complications by quadrupole interactions.

5 ELECTRONIC STRUCTURE OF MESOSCOPIC PARTICLES

5.1 Energy Levels

The energy spectrum of electrons confined in a finite volume is, in principle, discrete. In macroscopic metals, however, the spacing of the energy levels is very much smaller than the lifetime broadening of the levels, and, therefore, the continuous energy spectrum is a good approximation. The broadening caused by electron–phonon interactions and/or electron–electron interactions diminishes as the temperature is lowered, and typically becomes of the same order as thermal energy at 1 K. Thus, in small particles with an energy spacing larger than 1 K we would expect anomalies in electronic properties at temperatures below 1 K. The spacing is evaluated as

$$\delta = [N(E_F)\Omega]^{-1} \quad (8)$$

where $N(E_F)$ is the density of states at the Fermi level and Ω is the sample volume. In ordinary metals, Ω is $(10^4 \text{ pm})^3$ for δ to be 1 K.

Fröhlich was the first to point out anomalies in the thermodynamic properties in particles, assuming that the levels are equally spaced.²¹ Kubo took a more realistic level distribution, i.e. a random distribution. Kubo also put emphasis on the charge neutrality of particles because a single electron imbalance brings a large charging energy.²² Shortly after, Gorkov and Eliashberg suggested that the level distribution is not random but has statistical correlations, in analogy to the level distribution in heavy nuclei.²³ These correlations are the results of the symmetries of Hamiltonians governing the system.

Let $P(E) dE$ be the probability of finding the next level between E and $E + dE$. It can be shown that, in the limit of small E ,

$$P(E) = E^{n-1}/\delta^n \quad (9)$$

where n is the number of random variables. Four cases are possible:

1. case 1, $n = 2$: elements of the Hamiltonian matrix are real.
2. case 2, $n = 3$: in high magnetic fields where the elements are complex.
3. case 3, $n = 5$: with a strong spin–orbit interaction, where spin and orbital states are not separable.
4. case 4, $n = 1$: with a large Zeeman energy, where the levels of up and down spins are no longer correlated.

These discrete and correlated levels modify the electronic quantities such as spin paramagnetism, nuclear spin–lattice relaxation time, orbital diamagnetism, and specific heat. So far, the first two have been investigated both theoretically and experimentally. The specific heat is very difficult to measure accurately. There is a prediction that the orbital magnetization can be both positive and negative, and will fluctuate with a large amplitude when a magnetic field is swept,²⁴ but no experiment has been reported.

Figure 1 Temperature dependence of χ_{even} and χ_{odd} , with $\eta = (h/\tau_{\text{so}})^{27}$

5.2 Magnetism

The spin paramagnetism of small particles shows characteristic behaviors. For case 1, the spin susceptibility of a particle with an odd number of electrons, χ_{odd} , is Curie-like as $T \rightarrow 0$ because there is an electron that has no partner with opposite spin. The susceptibility of a particle with an even number of electrons, χ_{even} , tends to zero as $T \rightarrow 0$, as all the spins are paired with opposite ones. In case 2, χ_{even} revives because of the mixing of up- and down-spin states. The behaviors of χ_{even} and χ_{odd} are calculated with a finite strength of the spin–orbit interaction. The results are shown schematically in Figure 1. All anomalies in susceptibility vanish when $k_B T > \delta$.

The spin magnetization is nonlinear when the magnetic field is as high as $2\mu_B H \geq \delta$, because the level correlation is diminished.²⁵ Thus, when $2\mu_B H \geq \delta$, the spin magnetization will take a normal Pauli value.

Nuclear spin–lattice relaxation in metals is governed by the Korringa process, the relaxation time, T_1 , being inversely proportional to the temperature, reflecting the continuous energy spectrum of electrons. In small particles this process is strongly suppressed, because it is not always possible to conserve the energy through the process which involves a mutual flip of electron and nuclear spins and a change in electron orbital state.

5.3 Small Particles and Alloys

The first quantitative experiment of the Knight shift in small copper particles was reported by Yee and Knight.²⁶ The samples were particles that are formed on substrates at early stages of vacuum deposition. This method has been used for all the experiments described in this article. The distribution width of linear sizes of particles in each sample is about 20%

Figure 2 Temperature dependence of shifts in copper particles.²⁶ Particle diameters: $\circ$, 2.5 nm; $\bullet$, 4.0 nm; $\square$, 10.0 nm; $\triangle$, 11.0 nm

of its mean value. In Figure 2 the results of the Knight shift are shown for several samples. The temperature dependence and the size dependence of the residual shifts at $T = 0$ agree quantitatively with theory.²⁷

The spin–lattice relaxation time in copper particles was measured, and extraordinarily enhanced T_1 values were observed, as expected.²⁸

The suppression of the Knight shift anomaly in high magnetic fields (case 4) was confirmed in 10.0 and 6.0 nm copper particles.²⁹ The suppression was observed when $2\mu_B H \geq \delta$.

The spin scattering by magnetic impurities destroys the effects of level discreteness. To establish a kinetic energy level in a particle, an electron has to ‘see’ all the boundary conditions, i.e. it has to ‘sweep’ the whole volume of the particle. It can be shown that the time necessary for this travel is $\tau = \Omega/\pi v_F \lambda_F^2$, where v_F and λ_F are the Fermi velocity and the Fermi wavelength, respectively. If an inelastic scattering takes place before τ , the level cannot be sharp. The above expression for τ is equivalent to $\tau\delta = h$. This consideration can help interpret the results of the Knight shift of ^{63}Cu in particles of copper–manganese alloys.³⁰ The suppression of spin paramagnetic susceptibility disappeared when the manganese concentration was increased so that the spin scattering time is shorter than h/δ . The anomaly in T_1 also vanished.³¹

The strength of the spin–orbit interaction can be modified by alloying a heavy element in particles. The Knight shift was measured in copper particles alloyed with gold.³² As the concentration of gold increased, the Knight shift recovered the bulk value. Although this change is the same as that in copper–manganese, a substantial difference was observed in T_1 . The value of T_1 stayed very long even after the shift was completely recovered. This is because the spin scattering is inelastic while the spin–orbit scattering is elastic, the phase memory being retained in the latter.³¹

6 KNIGHT SHIFT IN SUPERCONDUCTORS

6.1 Spin Pairing

According to the BCS theory of superconductivity, the Knight shift quickly vanishes below the transition temperature,

because of spin–singlet pairing.³³ NMR experiments were intensively carried out to check the validity of the theory. However, in some superconductors of heavy metals the shift did not vanish but stayed finite when $T \rightarrow 0$. Soon after, it was recognized that this was a size effect. To measure the shift, samples of reduced dimension (thin films or fine powders) were used, in order to increase critical fields of superconductors of the first kind and to let the rf field penetrate the samples. The reduced dimension makes the mean free path shorter, and enhances mixing of up- and down-spin states due to spin–orbit interactions. Thus, for the same reason as for the residual Knight shift in normal heavy metal particles, the shift remains finite even when $T \rightarrow 0$.³⁴

6.2 Contributions to Shift

In transition metal superconductors the Knight shift consists of three contributions: the s band spin polarization, the orbital (Van Vleck) polarization, and the core polarization induced by non-s spin polarization. The first two are positive in sign, and the last is experimentally negative, although it can take both signs in principle. The three contributions can be resolved by observing the temperature dependence of the shift in the normal state. What is suppressed in the superconducting state is the first and the last polarization, while the orbital part does not change (cf. Section 3). A great deal of data has been accumulated for various superconductors.³⁵

6.3 How Small is a Superconductor

In the 1970s, the order parameter fluctuation in superconductors with reduced dimensions was exhaustively studied. Measured Knight shifts in aluminum particles smaller than the coherence length and penetration depth³⁶ agreed with microscopic theories for the critical region of temperature.³⁷ The result for aluminum particles is shown in Figure 3.³⁶ The theories were based on a grand canonical treatment, which is hardly applicable to small particles with a large charging energy, and does not take the discreteness of energy levels into account. As expected, substantial deviation takes place when the particles are smaller than 10.0 nm, in which δ is larger than the superconducting energy gap, Δ .³⁸

The residual Knight shift in tin particles as a function of particle size demonstrates the competition among three energy parameters, i.e. δ , Δ , and h/τ_{so} , where τ_{so} is the time within which the spin direction diffuses by an angle π due to spin–orbit interactions.³⁹ These energies are proportional to d^{-3} , d^0 and d^{-1} , respectively, d being a linear size. Therefore, Δ dominates in the bulk, and the shift vanishes. As the size is reduced, h/τ_{so} surpasses δ , and the shift (of particles with even number electrons) revives. With a further reduction, δ becomes the largest, and the shift disappears again. The experiment in tin particles with d ranging from 2.5 to 60.0 nm³⁸ clearly demonstrates this competition (Figure 4). The shift exhibits a peak at around 10.0 nm which corresponds to $\delta \sim \Delta$.

It is interesting to know how many atoms are necessary in small particles for superconductivity. Unfortunately, the level discreteness and the superconductivity modify the Knight shift (in particles with an even number of electrons) and T_1 in the same direction. A reliable way to judge the superconductivity

Figure 3 Temperature dependence of shifts in aluminum particles³⁶

Figure 4 Size dependence of residual shifts in tin particles³⁸

is to see if there is a sharp decrease in T_1 at an expected critical magnetic field for superconductivity. The results show that particles are superconductive even when $\delta \geq \Delta$. The observed critical fields support microscopic theories of pair breaking.^{39,40} Much smaller particles of aluminum with $\delta \sim 65$ K still exhibit superconducting features as long as T_1 is involved.⁴¹

6.4 High T_c

Since the discovery of high- T_c oxide superconductors, NMR has been used extensively to clarify the mechanism. The Knight shifts and relaxation times were measured for most of the constituent elements, such as ^{89}Y , ^{137}Ba , ^{63}Cu , and ^{17}O , in 'YBCO', yttrium barium copper oxide.

The main interest is to identify the nature of pairing, i.e. s wave or d wave pairing.⁴² Recently, there has been considerable debate on this question, which appears not to be settled as of March 1994. A complete understanding of the mechanisms operating in high- T_c materials still seems remote.

1 INTRODUCTION

Nuclear magnetic resonance is a useful tool with which to investigate certain important aspects of superconductivity. It has played an historic role in understanding the properties of superconductors. The environment of nuclear spins in a metal is greatly modified when a metal makes the transition into the superconducting state. The nuclear spins are sensitive to this variation, leading NMR to be an important technique as a probe of the superconducting state.

In a metal, the static response to an external magnetic field in the normal state is generally expressed by a bulk diamagnetic susceptibility. The same mechanism also contributes to the Knight shift of the NMR frequency in a metal.

The dynamic coupling between a spin system and its surroundings (the lattice) gives rise to lattice-induced transitions between spin states. The nuclear spin–lattice relaxation time T_1 is a measure of the rate of exchange of energy between a spin system and the rest of the lattice. It is most generally defined as the ratio of the deviation of spin energy from its equilibrium value to the time rate of change of spin energy.

The Knight shift and T_1 are two important quantities which give much information about the properties of conduction electrons. In particular, T_1 provides information on the density of states near the Fermi surface. Accordingly, it is expected that both effects provide a test of any theory of superconductivity.

Hebel and Slichter¹ first measured T_1 in aluminum, which was believed to be a well-behaved superconductor, in parallel with the development of the Bardeen, Cooper, and Schrieffer² (henceforth referred to as BCS) theory in 1957, which gave a microscopic understanding of superconductivity. They calculated the relaxation time predicted by the BCS theory, and found that their experimental T_1 data were consistent with the theory. In fact, T_1 measurements together with measurements of acoustic absorption provide an important confirmation of the choice of spin pairing of the BCS wavefunctions (the so-called ‘coherence effect’). The agreement of the nuclear relaxation time with theory is in contradiction to the behavior of the Knight shift, which remains finite in the superconducting state at absolute zero,^{3,4} a result that was difficult to explain in any simple way.

Independently, Redfield⁵ and later Masuda and Redfield⁶ measured T_1 in superconducting aluminum with greater

accuracy and over a wider temperature range, from which important information on the existence of an energy gap can be obtained. It was obvious that the nuclear T_1 values would be worth knowing, but these measurements were even more interesting than had been anticipated; they were in striking contrast to any two-fluid model of superconductivity, but could be easily explained by the BCS theory, assuming an energy gap at temperature $T = 0$ of $2\epsilon_0(0) = 3.2k_B T_c$ and a constant relative anisotropy of the energy gap, where T_c is the critical temperature. Studies of the superconducting state by NMR are summarized in detail elsewhere.⁷

2 KNIGHT SHIFT IN THE SUPERCONDUCTING STATE

2.1 Experiments on Elemental Superconductors

Soon after the appearance of the BCS theory, experiments on the ¹⁹⁹Hg Knight shift in mercury colloids³ and the ¹¹⁹Sn Knight shift in tin platelets were performed.⁴ The results for both Hg and Sn metals indicated the existence of a residual Knight shift at $T = 0$. These experiments seemed to contradict the BCS hypothesis of singlet spin pairing in the superconducting ground state. A number of explanations appeared to find a way out of this dilemma, involving ideas such as modified pairing criteria and even triplet spin pairing. To explain the experiments, however, a serious modification of the BCS picture was unnecessary.

In nontransition metals the Knight shift is due mainly to the hyperfine contact interaction, and is proportional to the normal state Pauli spin susceptibility χ_n . By making use of the BCS theory, Yosida⁸ calculated the spin susceptibility in the superconducting state and derived an expression for the Knight shift in the superconducting state.

In the superconducting state all ground state pairs are either occupied or unoccupied, and therefore the contribution to the spin susceptibility will only come from excited states, the populations of which are given by a Fermi function $f(E_k)$ of the excited state energy E_k . Accordingly, the spin susceptibility in the superconducting state is given by

$$\chi_s = -2\mu_B^2 \sum_k df/dE_k \quad (1)$$

where μ_B is the Bohr magneton and k the wavevector. By making use of the BCS energy density of excited states $N_{\text{BCS}}(E, T)$, the sums in equation (1) can be converted to integrals as follows,

$$\chi_s = -4\mu_B^2 \int_{\epsilon_0(T)}^{\infty} N_{\text{BCS}}(E, T) (df/dE) dE \quad (2)$$

Here $N_{\text{BCS}}(E, T)$ is given by

$$N_{\text{BCS}}(E, T) = \begin{cases} 0 & \text{for } |E| < \epsilon_0(T) \\ N(0)|E|/[E^2 - \epsilon_0^2(T)]^{1/2} & \text{for } |E| > \epsilon_0(T) \end{cases} \quad (3)$$

where $N(0)$ is the normal state density of states at the Fermi level. The χ_n value is obtained by taking $\epsilon_0(T) = 0$.

Figure 1 Spin susceptibility in pure superconducting aluminum. Filled circles: data of Fine et al.¹⁰ Solid curve: calculated from the theory of Yosida,⁸ l is the electron mean free path, and t is the average thickness of a single substrate

The early experiments of the ^{27}Al Knight shift showed that the Knight shift in the superconducting state at temperature $T = 0$, $K_s(T = 0)$ decreases to about 75% of its values in the normal state, K_n . This result suggested that a residual spin susceptibility, was conceivably due to an inclusion of paramagnetic impurities, since no other mechanism suggested itself. Hammond and Kelly⁹ repeated the measurement of the ^{27}Al Knight shift on stacked Al films, taking care to eliminate paramagnetic oxygen impurities in the film. The experimental result of $K_s(T)/K_n$ extrapolated to zero at $T = 0$, as shown in Figure 1,¹⁰ and the longstanding discrepancy between experiment and the prediction of singlet spin pairing, was thereby finally removed. Further experiments on the residual Knight shift in both tin and lead revealed that the spin-orbit coupling is induced in the conduction-electron gas by the boundary in small particles as well as imperfections, and the generalized pairing condition between time-reversed eigenstates might account for the small change of the Knight shift in the superconducting state.

2.2 Various Contributions to the Knight Shift

The conduction-electron susceptibility in the normal state of a metal consists of three important contributions: the s-band Pauli susceptibility in the case of a simple metal; the Van Vleck orbital susceptibility in transition metals with partly filled non-s bands; and the Pauli susceptibility of the non-s (usually d) bands in the case of transition metals. Each mechanism produces a shift component proportional to the corresponding susceptibility. The orbital shift is independent of the spin state of the conduction electrons, and hence does not change by spin pairing in the superconducting state. The contribution of the exchange interaction between non-s itinerant electrons and local s core electrons to the Knight shift should cancel each other out in the superconducting state if the d-band electrons take part in the formation of Cooper pairs.

The residual ^{51}V Knight shift in superconducting vanadium films is found to be intrinsically 100% of the normal state shift. This result indicates that the Knight shift due to the s-band

Pauli susceptibility and the Pauli susceptibility of the non-s bands must cancel each other, so that even if spin pairing is complete in the superconducting state, the effect on the measured Knight shift is small; the orbital shift is the principal contribution in both normal and superconducting states.

Susceptibility and Knight shift measurements on the inter-metallic compounds V_3Si and V_3Ga show that an increase of the ^{51}V and ^{71}Ga Knight shifts seen in the superconducting state can be attributed to a decrease of the d-band spin susceptibility at $T = 0$ to about 25% of its value at the critical temperature. V_3Si has the A15 crystal structure, in which an extremely narrow d-band exists. This crystal structure enhances the d-band susceptibility, which increases the Knight shift to well above its value in pure vanadium.

3 NUCLEAR SPIN-LATTICE RELAXATION IN BCS SUPERCONDUCTORS

3.1 Spin Relaxation due to the BCS Mechanism

The nuclear spin-lattice relaxation rate $R = 1/T_1$ in a type-I superconductor can be calculated within the framework of the BCS theory. The dominant mechanism for this relaxation process arises from the coupling of the nuclear spins I to the conduction electron spins σ , which are in equilibrium with the lattice, and the hyperfine contact interaction.

The matrix elements between excited states of the system are given by a single particle operator of the form

$$\hat{\mathcal{H}}_1 = \sum_{k\sigma, k'\sigma'} M_{k\sigma, k'\sigma'} \hat{a}_{k'\sigma'}^* \hat{a}_{k\sigma} \quad (4)$$

where $M_{k\sigma, k'\sigma'}$ is the matrix element corresponding to scattering from $k\sigma$ to $k'\sigma'$ and $\hat{a}_{k\sigma}^*$ and $\hat{a}_{k'\sigma'}$ are creation and destruction operators for quasiparticle excitations in the normal state. In the Bloch approximation, individual particle wavefunctions, $\phi_{k\sigma}(x)$, are defined for a self-consistent field. In this situation, therefore,

$$M_{k\sigma, k'\sigma'} = \int \phi_{k'\sigma'}^*(x) \hat{\mathcal{H}}_1(x) \phi_{k\sigma}(x) dx \quad (5)$$

in which x is defined to include the spin variable.

The significant feature of the BCS picture is the condensation of conduction electrons into a single, occupied ground state. In a pure metal this state corresponds to a pair occupation of the Bloch states $k\sigma$, such that if $k\sigma$ is occupied, so is $-k, -\sigma$ in the pair. At $T = 0$ all electrons occupy pair states; at finite temperature some pairs are broken up to form single-particle excitations. Nevertheless the coherent occupation of the condensed state restricts the scattering processes, and in addition alters the number of excited state electrons that can participate in scattering. Both these effects disappear in the normal state.

A remarkable difference between the superconducting and normal states arises from coherent effects associated with the paired wavefunctions. In the normal state scattering from $k\sigma$ to $k'\sigma'$ is completely independent of scattering from $-k', -\sigma'$ to $-k, -\sigma$, as well as of all other transitions. The probability of the former is proportional to $|M_{k\sigma, k'\sigma'}|^2$, and

the latter is $|M_{-k', -\sigma', -k, -\sigma}|^2$. Because of the nature of the paired wavefunction in a superconducting state, these two contributions to the matrix elements for transition probabilities in a superconducting state are coherent and therefore may add destructively or constructively.

The ground-state occupation changes the transition rate for scattering, in such a way that the transition rate in the normal state is modified by the factor

$$C_{\pm}(E_k, E_{k'}, T) = \frac{1}{2}[1 \pm (\epsilon_0^2(T)/E_k E_{k'})] \quad (6)$$

where E_k and $E_{k'}$ are the initial and final excited state energies, respectively. $C_{\pm}(E_k, E_{k'}, T)$ is the coherence factor, as it represents concretely the coherent nature of the population of pair states in the formation of the condensed phase. The sign of the second term in equation (6) depends on the nature of the perturbation which induces the transition. If the interaction is invariant under time reversal applied to the conduction-electron system, the minus sign is appropriate, namely $C_{-}(E_k, E_{k'}, T)$. This is the case for phonons; in the case of ultrasonic attenuation, there is a very rapid drop in attenuation versus temperature at T_c , followed by a more gradual decrease. If the perturbation is not time-reversal invariant, $C_{+}(E_k, E_{k'}, T)$ is appropriate. The nuclear spin relaxation rate exhibits an increase by a factor of 2 just below T_c which gives an indication of coherence effects arising from constructive interference.

Consider, for simplicity, that $I = \frac{1}{2}$, and that an experiment is performed in a magnetic field with nuclear Zeeman energy $\hbar\omega_{\text{nuc}}$. Then the relaxation rate is given by $W_{+} + W_{-}$, where W_{+} is the transition rate from spin-up to spin-down nuclear states induced by the entire conduction-electron system, and W_{-} is the rate for spin-down to spin-up transitions. The relaxation rates are given by

$$W_{\pm} = \frac{\pi}{2\hbar} |M_{k\sigma, k'\sigma'}|^2 \sum_{k, k'} C_{\pm}(E_k, E_{k'}, T) f(E_k, T) \times [1 - f(E_{k'}, T)] \delta(E_{k'} - E_k \mp \hbar\omega_{\text{nuc}}) \quad (7)$$

where the Fermi distribution function $f(E_k, T)$ accounts for the thermal population of excited initial states, and $[1 - f(E_{k'}, T)]$ gives the thermal depopulation of final states required by the Pauli principle. The delta function insures the conservation of total energy in the scattering process.

By making use of the density of states in the superconducting state $N_s(E_k, T)$, the sums in equation (7) can be converted to integrals. The relaxation rate in the superconducting state R_s is given by

$$R_s \propto \int_0^{\infty} N_s(E_k, T) N_s(E_{k'}, T) [1 + \epsilon_0^2(T)/E_k E_{k'}] f(E_k, T) \times [1 - f(E_{k'}, T)] dE_k \quad (8)$$

The BCS theory shows that the superconductor has a temperature-dependent gap of halfwidth $\epsilon_0(T)$ centered about the Fermi energy E_F . If the difference in energy between final and initial electron states is ignored, then the ratio of relaxation rates in superconducting to normal states, R_s/R_n , is given by

$$R_s/R_n = 2 \int [N_s(E, T)]^2 [1 + \epsilon_0^2(T)/E^2] f(E, T) \times [1 - f(E, T)] dE \quad (9)$$

There is actually a logarithmic divergence of the integral in the limit $\hbar\omega_{\text{nuc}} \rightarrow 0$. This divergence comes from the singularity in the BCS density of states at the edge of the energy gap. The values of T_1 in the superconducting state predicted directly by the BCS theory are thus much shorter than those observed, and much shorter than T_1 in the normal state, near T_c . In comparing the theory with experiment it is necessary to take some sort of width for the electronic levels. It is reasonable that in actual metals the singularity will be removed by some mechanisms, and it is possible to see that spin-lattice relaxation measurements can yield information on the nature of such mechanisms.

Hebel and Slichter¹ obtained N_s by weighting the BCS density of states, N_{BCS} , with a function that characterizes the breadth of the energy levels. If an energy level breadth function is assumed to be a rectangle of width 2Δ and height $\frac{1}{2}\Delta$, then

$$N_s(E, T) = (2\Delta)^{-1} \int_{E-\Delta}^{E+\Delta} N_{\text{BCS}}(E', T) dE' \quad (10)$$

Using equation (9), we can calculate the temperature dependence of T_1 for various values of $r = \epsilon_0(0)/\Delta$. Actually, of course, the parameter Δ might be temperature dependent. Now, as T approaches T_c the gap $2\epsilon_0(T)$ decreases, and it would be natural to assume that the anisotropy decreases and is perhaps proportional to the gap, as pointed out by Masuda and Redfield.⁶ In that case we would have $\Delta(T)$ proportional to $\epsilon_0(T)$.

A field cycling method was used to measure T_1 . In this method a large field is applied across the sample to polarize the nuclei (about 0.4 T in this case) for a time long compared with T_1 . The field is then reduced to zero in a time that is short compared with T_1 , and the spins begin to relax at zero field in the superconducting state with a relaxation time characteristic of the superconducting state. After a variable time τ , the field is then turned on again (to about 0.1 T) and immediately swept past the present resonance field of 0.1045 T to observe the spin polarization in the normal state by nuclear resonance. The resonance intensity is proportional to the spin polarization at that time and from its variation of the resonance signal intensity with τ , the relaxation time can be determined.

The nuclear resonance signal obtained in this way is much smaller than that observed above T_c because the nuclei are partially irreversibly demagnetized by the sudden change in magnetic field to which they are subjected when the transition takes place between the normal and superconducting states. For the sample used in most of these measurements, the signal was reduced to less than 5% of the value it would have had in a similar nonsuperconductor after the same sequence of field cycling.

The data for the relaxation time in both normal and superconducting states are shown in Figure 2 as a function of T_c/T .⁶ The fact that T_1 decreases markedly just below T_c , and then increases as $\exp[\epsilon_0(0)/k_B T]$ for $T \ll T_c$ is a rather general consequence of any gap model. As can be seen from Figure 2, superconducting aluminum has an energy gap at $T = 0$ of $2\epsilon_0(0) = 3.2k_B T_c$, assuming that the BCS density of states function is smeared over a range of about $\Delta(T) = \epsilon_0(T)/10$, or $r(T) = 10\epsilon_0(0)/\epsilon_0(T)$. The BCS theory applies to the homogeneous, pure, and isotropic electron gas with a simplified interaction term and pure plane wavefunctions. If,

Figure 2 Measured values of T_1 in a powdered, pure aluminum sample.⁶ T_c was taken to be 1.178 K. The solid line was calculated using the BCS density of states smeared over a range of 1/10 of the energy gap, assuming a smearing proportional to the energy gap

instead of the constant electron–electron interaction, one were to use wavefunctions and an electron–electron interaction that is nonconstant and anisotropic (as might be expected in actual metals), one would expect to find that the energy gap is a function of momentum vector, as well as temperature. Thus, the energy gap of a single particle excitation would depend upon the direction, as well as the magnitude, of its momentum vector. But nuclear spin relaxation has no momentum selection rule for the initial and final states of the transition, so the average density of states determines T_1 , not the density of states in any particular k direction. Thus, as far as spin relaxation is concerned, the effect of anisotropy is to smear the BCS density of states by an amount equal to the anisotropy.

These experimental data are regarded as evidence for the existence of an anisotropy in the energy gap which, at any temperature, is of the order of one-tenth of the gap itself. The quantity $\Delta(T)$ could be interpreted in some other way, such as an inverse lifetime for scattering by imperfections or electrons. However, the temperature dependence of Δ or r is most naturally explained in terms of anisotropy. The anisotropy interpretation is also supported by the results described in the next section.

Measurements of T_1 in superconductors were extended to cadmium,¹¹ for which the behavior is practically identical with that of aluminum.

3.2 Impurity Effects: Anisotropy of the Energy Gap

The T_1 data of both superconducting aluminum and superconducting cadmium were explained very well by assuming a smearing of the anisotropy of the gap as mentioned above. To confirm this assumption experimentally, T_1 in superconducting aluminum alloys was measured.¹²

Figure 3 Measured values of T_1 in Al–Zn alloys.¹² T_c was taken to be 1.178 K. The solid lines are calculated using the BCS density of states smeared over a range of 1/10, 1/40, and 1/60 of the energy gap, assuming a smearing proportional to the energy gap

In a dilute alloy, plane-wave states with fixed spin are no longer good one-electron wavefunctions. Anderson¹³ developed a BCS type of theory for dirty superconductors, in which elastic scattering from physical and chemical impurities is large compared with the energy gap. He argued that a ground-state pair should be formed by pairing a one-electron state with its exact time reversed. This state is a generalization of the k up, $-k$ down pairing of the BCS theory, which is independent of impurity scattering. If the electronic mean free path is large compared with the coherence length, the impurities will mix plane-wave states weakly as the electron moves through a coherence length. However, when the mean free path is small compared with the coherence length, the wavefunction can no longer be approximated by a single plane wave. Thus, the states are taken more or less randomly from all parts of the Fermi surface, thereby removing this source of anisotropy in the energy gap.

The experimental data on Al–Zn alloys are shown in Figure 3. The data on the 0.036 at% Zn alloy agree well with theory, assuming $r(T) = 40\epsilon_0(0)/\epsilon_0(T)$ and using the same energy gap $2\epsilon_0(0) = 3.2k_B T_c$ as that used in pure bulk aluminum (solid line). Data on the 0.055 at% Zn alloy show that a numerical factor in $r(T)$ increases from 40 to 60 but the energy gap remains the same. Roughly speaking, the increase of the numerical factor is proportional to the inverse mean free path $1/l$.

As we add impurities, the individual momentum states are scattered around the Fermi surface. Therefore, the angular dependence of the energy gap is removed from the individual excitation energy gap. If Δ represents an anisotropy of the energy gap present in pure aluminum, Δ decreases (or r increases) as the impurity concentration increases. For sufficiently small concentrations of impurities, the experimental data indicate that r increases linearly with increasing reciprocal mean free path. This apparent linear increase of r with l^{-1}

may be fortuitous, since the accuracy of the present determination of r is poor. Presumably the quantity r^{-1} is a measure of the anisotropy.

Data on a 0.16 at% Ge alloy indicate that the width of the energy gap will be close to the value predicted by BCS theory in the case of constant interaction. Once the mixing is complete, the effect on superconductivity should saturate. If we could measure T_1 in very impure samples without quadrupolar effects, the saturation value of r might be observed. But, as T_1 is proportional to $\log r$ for $T \ll T_c$, it would be hard to determine r correctly.

The theory of energy gap anisotropy in dirty superconductors was given by Clem.¹⁴ The gap parameter in the direction θ can be defined as

$$\epsilon_0(\theta) = \langle \epsilon_0 \rangle [1 + a(\theta)] \quad (11)$$

where $a(\theta)$ is the anisotropy function which describes the variation of the gap over the Fermi surface due to anisotropy in the phonon spectrum or the band structure, and $\langle a(\theta) \rangle = 0$. The density of excited states is calculated as a function of the impurity scattering mean free path, or specifically of the ‘dirtiness’ parameter

$$y_D = [2\epsilon_0(0)\tau]^{-1} = 1.57\xi_0/l \quad (12)$$

where τ^{-1} is the mean frequency of scattering processes and ξ_0 the coherence length. In the dirty limit, $y_D \gg 1$, the density of states approaches the singular BCS form, and by making use of the mean square anisotropy $\langle a^2 \rangle$, becomes a universal function of the parameter $\eta_s = y_D/\langle a^2 \rangle$. The anisotropy-induced structure in the density of states will disappear in the dirty limit.

3.3 Size Effect: Fluctuations in the Order Parameter

Measurements of the Knight shift in superconductors must, of necessity, be made on samples that are small compared with the penetration depth in order that variations in the Knight shift will not be confused with the shift due to the Meissner effect. In contrast to the Knight shift, measurements of T_1 are in good agreement with the BCS theory; these measurements have been made on ‘bulk’ samples, that is, powders with individual particles that are large compared with the coherence length. In view of the disagreement between the Knight shift measurements and the BCS theory, it seemed interesting to see if there is an anomaly in the relaxation time as well, when the particle size becomes small compared with the coherence length or the penetration depth. This was the motivation for performing experiments on the size effect.¹⁵ However, the experimental results obtained surpassed our expectations and suggested an important and interesting fact of superconductivity, which is yet to be theoretically understood.

Particles of aluminum having diameters of less than 2000 Å were prepared by vaporizing aluminum in an atmosphere of argon at a pressure of a few hectopascals. Then the relaxation time T_1 was measured by using the field cycling method in the normal and superconducting states between 0.36 and 1.3 K. In the normal state, and near T_c , the relaxation time was nearly the same as for bulk aluminum, which is evidence that the particles are indeed metallic.

Figure 4 Measured relaxation times T_1 in pure aluminum colloid, the diameter of which ranges from 200 to 700 Å¹⁵

Typical T_1 results for the sample with the most uniform particle size distribution (200–700 Å) are shown in Figure 4.¹⁵ The relatively small change in T_1 in the normal state, compared with the bulk sample, may be the result of an imperfection-induced quadrupole interaction. However, such a change was not observed when small amounts of impurities were added to bulk samples, so the change may be a true size effect.

Kubo¹⁶ discussed the specific heat and spin susceptibility of small particles, but probably his conclusions did not apply to particles as large as those used here. It is interesting to note that the electronic level spacing in the particles is large compared with $\hbar/T_1$, in violation of the condition for the validity of time-dependent perturbation theory. This difficulty can probably be ignored since the electronic levels are broadened by interaction with lattice vibrations, so that the system, electrons plus lattice, has a higher density of states than the electrons alone.

Turning to the superconducting state, the zero field measurements can be fitted to a theoretical curve according to the procedures applied to the bulk metal described before. Well below T_c , the zero field relaxation time is shorter than that of bulk aluminum, being less than one-fifth the bulk value at 0.4 K, and indicates a gap of the order of one-half the BCS value. Thus, an important size-dependence of T_1 was found, but these results could not be explained in a satisfactory way at that time, and were forgotten. About 10 years later, this relaxation behavior was explained by considering the effects of fluctuations of the order parameter in small specimens. The first observation, made in 1967,¹⁷ attributed to fluctuations, was an increase in conductivity just above T_c in thin films. A theoretical explanation of the observation was given in 1968.¹⁸ A reduction in the size of specimens should increase the effect of fluctuations in the order parameter. Therefore, the most suitable specimens for the observation of the size effect are small isolated particles.

Maki et al.¹⁹ first considered the effect of fluctuations on nuclear spin–lattice relaxation in superconductors in the mean field regime. They found an expression for the relaxation rate

Figure 5 Reduced relaxation time $T_1/T_{1n}(T_c)$ as a function of inverse reduced temperature, reduced pair-breaking parameter α/T_c , and particle size parameter $\bar{\delta}$. Light solid curves: unrenormalized theory of Maki et al.¹⁹ Heavy solid curves: renormalized dirty-limit theory of Simánek et al.²¹ Open circles and triangles: experimental results of Masuda and Redfield (annealed and unannealed aluminum colloids, respectively). The diameter ranges from 200 to 700 Å¹⁵

above T_c in the presence of fluctuations given by,

$$R_s/R_n = 1 + [\pi T_c/4N(0)v\alpha(H)(T - T_c)] \quad (13)$$

where v is the particle volume and $\alpha(H)$ a pair-breaking parameter. Pair-breaking may be due to paramagnetic impurities, an applied magnetic field, or, in the absence of external perturbations, the small, spatial variation of the order parameter near the particle surface. According to equation (13), the relaxation rate diverges as $(T - T_c)^{-1}$ at $T = T_c$ as shown in Figure 5. This divergence is removed by allowing the normal electrons to be dressed with fluctuation-induced Cooper pairs. Using this picture, the spin-lattice relaxation rate was calculated.²⁰ The effect of renormalization of the normal electrons by fluctuations extended over a much wider temperature range than interactions between fluctuations themselves. Thus, the divergent behavior was removed.

The temperature dependence of R_s shows a smooth behavior in the region of T_c for all values of v and $\alpha(H)$. The size parameter is defined as $\bar{\delta} = 1/N(0)vT_c$. For small $\bar{\delta}$ a characteristic peak is obtained in the relaxation rate just below T_c . As $\bar{\delta}$ is increased, this peak is smeared out, and the rate decreases monotonically with decreasing temperature for $\bar{\delta} \lesssim 1$. For $\alpha(H) \neq 0$, the position of the peak is depressed to lower temperatures if $\bar{\delta} \ll 1$, and for $\bar{\delta} \lesssim 1$ the effect of additional pair breaking is a small increase in R_s . These results are shown in Figure 5.²¹

This theory is not appropriate for very small particles ($\bar{\delta} \gtrsim 1$), since here the level quantization imposed by the boundary conditions on the electronic wavefunctions at the particle surfaces splits the electronic energy levels by an amount comparable to T_c . This effect is important for Al and Sn particles of less than 50 Å in diameter.^{22,23} The

theory, in which the combined effect of fluctuations and level quantization are taken into account, is quite complicated.²⁴

4 NMR IN TYPE-II SUPERCONDUCTORS

4.1 Magnetic Field Distribution in the Mixed State

A change in NMR properties in the mixed state is caused by the penetration of a magnetic field into a type-II superconductor by means of a periodic lattice of fluxoids, or vortices. Conventional NMR studies of the field distribution are difficult because of the large resonance linewidths, baseline drift, and noise due to vortex motion. To avoid these difficulties the same field cycling method as that used in superconducting aluminum was used. This method has the advantage that the signal can be observed in the normal state with less noise and baseline drift.²⁵ In the case of type-II superconductors the magnetic field was not reduced to zero but switched to a value below H_{c2} during a time τ which was fixed at about 0.1 s. During the time τ a transverse rf field $H_p \cos(2\pi\nu_p t)$, the probe field, was applied perpendicular to H_c . In order to measure the effect of the probe field, the decrease in this subsequent signal reflecting the NMR absorption was measured as a function of the probe frequency ν_p . Typical subsequent signals are shown in Figure 6.

The original calculation on the vortex lattice structure performed by Abrikosov assumed a square lattice. The first direct evidence for the vortex lattice was a neutron diffraction experiment and it was concluded that the lattice must be

Figure 6 Raw lineshape data at various fields and power levels in type-II superconducting vanadium²⁵

Figure 7 Theoretical resonance lineshapes.²⁵ The inset shows a unit cell of the triangular vortex lattice, showing points of maximum field (V), minimum field (C), and the saddle point (S)

triangular. The first calculation of the NMR lineshape was performed for a square fluxoid lattice and appeared to conflict with the NMR data. The theoretical resonance lineshapes for the triangular and square lattice are shown in Figure 7. The calculation was performed on the basis of a solution to the Ginzburg–Landau equation in the Abrikosov limit. The difference between the positions of the singularity for the square and triangular lattice is a general result of geometry plus the assumption that field and current cannot vary in space over a coherence length. The inset shows a unit cell of the triangular vortex lattice, showing points of maximum field (V), minimum field (C) and the saddle point (S). For the square lattice, the saddle point in real space is equidistant from the nearest vortex and the nearest minimum point. For the triangular lattice, in real space, the saddle–vortex distance (S–V) is $\sqrt{3}$ times greater than the saddle–minimum distance (S–M). Thus the saddle point field also tends to be closer to the minimum field, an effect that is much greater than the real space distance ratio suggests, because the field and current must vary smoothly in space.

The theoretical lineshapes in Figure 7 were convoluted with a Gaussian function to smear out the lineshapes by about 10%, in order to agree with the width of the end of the line at high field, and then normalized to obtain good agreement with experiment for the triangular lattice, as shown in Figure 8. The experimental points are proportional to $-\ln \{[S(H_p) - S(\infty)]/[S(0) - S(\infty)]\}$, where $S(H_p)$ is the signal observed when the probe field equals H_p , $S(0)$ is that with no probe field, and $S(\infty)$ is the signal at very high probe power, which is mostly due to repolarization of the spin system during the time the field is turned on, just before observation, at 0.6 T. If one makes a simple spin-temperature assumption about the rate of energy absorption, then one concludes that this transformation of the data should give the absorption lineshape that would be observed in conventional NMR. The excellent agreement between these points and the triangular lineshape should not be taken too seriously, since there were three parameters varied to fit the data (width, height, smearing), but it would not be possible to change these parameters to get nearly as good agreement with the square lattice curve. Closer to H_{c2} it would be harder to make this distinction. For very low magnetic field, however, one has essentially an array

Figure 8 Comparison between theoretical lineshapes obtained by smearing the shapes of Figure 7, with the absorption lineshape deduced from the data of Figure 6²⁵

of nearly isolated vortices, and the peak is expected to move toward the lower end of the line for any arrangement.

Similar work using a standard continuous-absorption technique was performed by Delrieu and Winter.²⁶ They observed the ^{73}Nb resonance in superconducting niobium near H_{c2} , directly, and found a field distribution with the singularity near the minimum field value, as predicted for the triangular lattice, which agrees well with the conclusion by Redfield.

4.2 Nuclear Magnetic Relaxation in Type-II Superconductors

The nuclear spin–lattice relaxation time, T_1 , in a type-I superconductor in zero magnetic field is determined mainly by the high density of states above the energy gap. For a type-II superconductor, the energy dependence of the density of states in the mixed state slightly below the upper critical field H_{c2} differs considerably from that in the BCS state. In the Abrikosov description of type-II superconductors in the mixed state, an external magnetic field penetrates into the specimen as quantized flux, called fluxoids or vortices. In the region of a fluxoid, the order parameter is appreciably reduced from its zero field value, approaching zero at the flux center. This reduction in the order parameter may be reflected in the density of states near the Fermi surface and hence the behavior of the nuclear spin relaxation rate.

Measurements of T_1 in a type-II superconductor were expected to add information to the picture of the mixed state. In earlier studies in the mixed state, most T_1 measurements were made far below H_{c2} and T_c .²⁷ This situation corresponds to the case of well-separated vortices. In the absence of vortex motion and spin diffusion, the nuclear spins located far from vortex lines certainly see quasiparticle excitation in a superconductor, and at low temperatures will show BCS behavior. Spins within the coherence length ξ_0 of a vortex

line relax rapidly with a rate comparable to the normal state value. When both spins contribute significantly to the signal, nonexponential decays will be observed. Experiments on Nb–Zr alloys indicate that the slow decay component of the signal, which is attributed to the spins located far from vortices, shows BCS behavior. In this case, the spatial fluctuations of the energy gap are considered to be localized near the flux center and most of the sample has an energy gap which is essentially equal to that in zero external field. As the temperature decreases T_1 begins to deviate from the BCS value appreciably. The field-dependent deviation from the BCS theory was attributed to a relaxation mechanism involving spin diffusion to the vortex cores. In the subcritical region slightly below H_{c2} , the distance between vortices becomes comparable to the coherence length ξ_0 . In this region, the order parameter $\epsilon_0(r)$ is small and a gapless excitation spectrum is expected to appear. It is therefore likely that the nuclear relaxation in this region will show interesting features.

The T_1 of ^{51}V in an intermetallic compound V_3Sn was measured by pulsed NMR in the temperature range 1.2–77 K.²⁸ The measurements were carried out at the center of the resonance from 0.4470 to 1.3410 T for frequencies of 5, 10, and 15 MHz. The Korringa relationship $T_1 T = 420 \text{ ms} \cdot \text{K}$ was well fitted by the experimental points taken in the normal state over the temperature range 1.8–77 K for a magnetic field of 1.3410 T. At the critical temperature corresponding to this field (1.8 K), T_1 showed no minimum as the temperature decreased but it increased monotonically compared with the Korringa time.

The experimental results in the range 1.2–4.2 K are shown in Figure 9 in the form of the ratio R_s/R_n as a function of $T/T_c(H)$, at a fixed magnetic field. $T_c(H)$ is the critical temperature corresponding to the resonance field H . As can be seen from Figure 9 in the case of $T_c(0) > T_c(H) > 0.6T_c(0)$, a maximum in $R_s(T)/R_n(T)$ appears at $T/T_c(H) = 0.9$ in both cases of 0.4470 and 0.8940 T, but the magnitude of this maximum is dependent on the applied field strength. However, in the case of $T_c(H) < 0.6T_c(0)$, $R_s(T)/R_n(T)$ shows no maximum as the temperature decreases, but it decreases exponentially. This effect of magnetic field on the relaxation behavior suggests that a pair-breaking mechanism due to magnetic field enters into the coherence factor.

Griffin and Ambegaokar²⁹ have extended the calculation of the nuclear spin relaxation rate to a superconductor in the presence of magnetic impurities. The conclusion that the coherence factor is due to the nature of the magnetic hyperfine coupling between the electrons and the nuclear spins is important. The superconductor containing magnetic impurities is a perfect diamagnet in an external magnetic field even in the gapless region. The fundamental property of superconductivity is thus the existence of a pair correlation rather than that of an energy gap. The most important effect of superconductivity appears only through the coherence factors. It is known that paramagnetic impurities and magnetic fields have similar effects on many physical quantities in superconductors. In these two situations the coherence factors are equivalent. This equivalence is established only for the second-order term in $\epsilon_0(r)$ and significant deviations are expected to arise in the fourth order terms. The depairing by the magnetic field or by impurities enters into the coherence factors and these pair-breaking mechanisms are equivalent in both cases. Starting

Figure 9 Reduced ^{51}V relaxation rate in the superconducting mixed state of V_3Sn . The relaxation rate for a magnetic field of 1.3410 T decreases monotonically with temperature²⁸

from this point of view, Maki and Fulde³⁰ obtained the results equivalent to those derived by Griffin and Ambegaokar.²⁹

The ratio of the nuclear spin relaxation rates in a dirty type-II superconductor in the gapless region to those in the normal state were obtained by Cyrot³¹ using a perturbation calculation in powers of $\epsilon_0(r)$. He obtained the following result,

$$\frac{R_s}{R_n} = 1 + \frac{\langle |\epsilon_0(r)|^2 \rangle}{2(2\pi k_B T)^2} [\rho^{-1} \phi^{(1)}(\frac{1}{2} + \rho) + 3\phi^{(2)}(\frac{1}{2} + \rho)] \quad (14)$$

where $\rho = D_e H / (2\pi k_B T)$, D is the diffusion coefficient, and $\phi^n(\rho)$ is the n th derivative of the digamma function. If we substitute the expression for $\langle |\epsilon_0|^2 \rangle$, following Abrikosov, equation (14) in the case of spherical samples can be represented as follows:

$$\frac{R_s}{R_n} = 1 + \frac{ec}{8\pi^2 \sigma k_B T_c(0)} - \frac{H_{c2} - H}{[2\kappa_2^2(t) - 1]\beta_A + \frac{1}{3}} C(t) \quad (15)$$

where σ is the normal state conductivity, c the velocity of light, $\kappa_2(t)$ the temperature-dependent parameter which appears in the expression for the magnetization, $\beta_A = 1.16$, and $C(t)$ is a dimensionless function of reduced temperature $t = T/T_c(0)$ given by

$$C(t) = (\rho t)^{-1} \left[1 + 3\rho \frac{\phi^{(2)}(\frac{1}{2} + \rho)}{\phi^{(1)}(\frac{1}{2} + \rho)} \right] \quad (16)$$

The temperature dependence of $C(t)$ was numerically calculated, and depicted in Figure 10. In the range of $t = 0$ to 0.6, $C(t)$ has a negative value and crosses zero at $t = 0.6$. As the

Figure 10 Dependence of the universal function $C(t)$ on the reduced temperature $t = T/T_c$. The gradient dR_s/dH of the relaxation rate at H_{c2} is proportional to $C(t)$ in the mixed state of dirty type-II superconductors³¹

temperature increases above $t = 0.6$, $C(t)$ becomes positive, and then diverges near $T_c(0)$.

As can be understood from equation (16), in the range of $H_{c2} - H \ll H_{c2}$ and for temperatures close to $T_c(H)$, the relaxation rate in the superconducting state is larger than that in the normal state. For temperatures far below $T_c(H)$, the relaxation rate in the superconducting state becomes smaller than R_n . At $0.6T_c(0)$ both rates have the same value. This behavior agrees with the experimental result that at about $T = 0.6T_c(0)$ the slope of the relaxation rate passes through zero.

The theoretical prediction of the initial slope of the relaxation rate at $T_c(H)$ for the magnetic field, in which the relaxation rate is measured, is given by the following equation:

$$\left. \frac{1}{R_n} \frac{\partial R_s}{\partial T} \right|_{T=T_c(H)} = \frac{ec}{8\pi^2 \sigma k_B T_c(0)} \left. \frac{\partial H_{c2}(T)}{\partial T} \right|_{T=T_c(H)} C(t) \quad (17)$$

The calculated result described above agrees with experiment quite well at low temperatures. However, a deviation appears near $T_c(0)$. One of the reasons for this deviation may be the broadening of the BCS state due to energy gap anisotropy.

4.3 Magnetic Impurity Effects in Type-II Superconductors

Magnetic impurity effects, studied by NMR in metals and alloys, give much information about the electronic states of conduction electrons. In normal metals and alloys, various paramagnetic impurity-induced relaxation mechanisms exist, in addition to the usual Korringa process. They are the relaxation due to the fluctuating local dipole fields associated with the longitudinal and transverse fluctuations of the localized magnetic impurity dipole moment (the LD and TD mechanisms); and the indirect Rudermann–Kittel–Kasuya–Yosida coupling between the localized magnetic impurity moment and nuclear spins via conduction-electron systems. The latter relaxation mechanism is associated with the real or virtual excitation of the localized magnetic impurity moment (the RE and VE mechanisms), respectively.

Superconductivity is strongly affected by the presence of magnetic impurities. The Korringa mechanism in superconductors has been investigated theoretically within the framework of the Abrikosov and Gor'kov (AG's) depairing theory by Griffin and Ambegaokar.²⁹ The LD, TD, RE and VE mechanisms also play an important role in the superconducting state.³²

According to the observed macroscopic properties, Gd impurity possesses a well-defined spin and affects the superconducting properties in the way expected by the AG theory. Cerium impurity, however, shows the anomalies associated with the Kondo effect. In particular it seems very interesting to investigate microscopically by NMR the differences of the pair-breaking effects between the Gd and Ce impurities.

The relaxation rate R_s in a Kondo superconductor has been calculated numerically in the framework of the Müller–Hartmann–Zittartz depairing theory.³³ The theoretical temperature variation of R_s is expected to show very interesting behavior, corresponding to the reentrance behavior of superconductivity.

The host ^{27}Al nuclear spin–lattice relaxation in the normal and superconducting states of the $(\text{La}_{1-n}\text{Gd}_n)_3\text{Al}$ and $(\text{La}_{1-n}\text{Ce}_n)_3\text{Al}$ systems has been studied in detail.³⁴ The conclusions obtained are: (1) the impurity-induced relaxation rates play an important role in ^{27}Al relaxation and can be well interpreted by the LD mechanism for both the Gd and Ce doped systems; (2) the measured relaxation rates show large enhancement in the superconducting state. This seems to arise from the change of the impurity spin relaxation time. Quantitative analysis shows that the impurity spin dynamics is determined by the relaxation mechanism arising from the s–f exchange interaction between impurity spin and conduction electrons even in the superconducting state; and (3) in the vicinity of the transition temperature the observed temperature variation of T_1 seems to show a large discrepancy in comparison with the prediction of the impurity pair-breaking theory both in the Gd and Ce doped systems.

1 INTRODUCTION AND BACKGROUND

1.1 The Beginning of NMR in Metals: Investigators and Material

The discovery of the resonance of nuclei is so recent that the number of subspecialties that have developed is astounding. In large part it represents the number of working scientists during the intervening years. In addition, the time period is one during which solid state physics, polymer physics, and more recently the biological sciences have seen unprecedented advance.

The discovery of the fact that proton resonance could be observed with relative ease if the required conditions were understood led two independent groups to construct apparatus to search for, and to find, the phenomenon in the same year. Fortunately, nuclear physics had a long history of research culminating in a burst of activity in the early 1940s. Tables of nuclear moments were available and there was an immediate spread of NMR to a host of elements in the Periodic Table. Pound saw the Cu metal resonance from the wire of his rf spectrometer¹ and Knight² soon after found that Cu metal and the corresponding isotopes in CuCl were at different frequencies in the same external magnetic field. Nuclear magnetic resonance in metals was thus launched only two years after the first nuclear resonance observation of hydrogen. The latter required the knowledge and skill of brilliant scientists, each of whom received a (shared) Nobel prize. Reading the Nobel prize acceptance speeches is rewarding, as is the study of the papers of Purcell et al. and Bloch et al. published in *Physical Review* in 1946.

Workers in the field of NMR in metals require an interdisciplinary background strong in physics, especially the theory of the solid state, and also well-developed in metallurgy. The latter subject remains one in which few phenomena are derived a priori, and the words 'experience' and 'art' are sometimes necessary to describe the methods successfully used in specimen preparation. Complex studies that purport to demonstrate a correlation between an NMR result and a particular aspect of the behavior of a metal or alloy should assume from the outset that the physical property under investigation must be measured on a batch of material prepared

for the study, and that the NMR must be conducted on samples from the same batch. An example study might be the rate of internal oxidation measured using resistivity or susceptibility together with NMR absorption line parameters. Correlation of NMR results with mechanical properties (rather than electrical) is usually more difficult.

1.2 Metals and Nuclei

The metallic state has several familiar but different characteristic mechanical and electrical properties when compared with other solid types. If we consider the four classic types of solids, metallic, ionic, covalent, and molecular (or van der Waals),³ the metals are known to be highly ductile, good electrical and thermal conductors, and different in their magnetic properties from ionic and covalent solids. The underlying reasons for the physical properties of metals lies almost entirely in their electronic structure. In solids which are primarily ionic or covalent the bonding potentials are largely central or directional, respectively. Metals by contrast are held together by nondirectional atomic potentials. Nearly all metals have one atom per lattice site, and thus have structures in which the atoms lie on the points of a Bravais lattice.⁴ Not surprisingly most metals have lattice structures in which the atoms are arranged as closely packed spheres [face centered cubic (fcc) and hexagonal close packed (hcp)]. The next most common structure among metals is body centered cubic (bcc). Of the roughly 50 metals in the Periodic Table about 36 are close packed and 14 bcc. Nearly *all* of these metals have at least one isotope which is useful for NMR, i.e., it has nonzero nuclear spin I , and thus a nonzero nuclear magnetic moment $\mu = \gamma_I \hbar I$, where γ_I is the nuclear gyromagnetic ratio and $\hbar = \text{Planck's constant divided by } 2\pi$. The majority of metals have more than one isotope of $I > 0$ (i.e., from among $I = \frac{1}{2}, 1, \frac{3}{2}, 2, \dots$). Isotopic abundance is a crucial factor in considering the feasibility of observing the nuclear resonance of a particular metal.

In addition to a magnetic dipole moment μ , a majority of nuclei have an observable electric quadrupole moment Q . In brief form there are two restrictions that limit the observability of electrical multipole moments:⁵ (a) No odd (l odd) electrical multipole (2^l -pole) moments can exist, and (b) for a nuclear spin I , it is impossible to observe a nuclear multipole moment of order 2^l greater than that corresponding to $l = 2I$. (The result of these restrictions is that we can expect to observe no dipole, octupole, ... electrical moments; and that for $I = \frac{1}{2}$ we can observe no multipole greater than dipole, for $I = 1$ we can observe no multipole greater than quadrupole, for $I = \frac{3}{2}$ we can observe no multipole greater than octupole, for $I = 2$ we can observe no multipole greater than hexadecapole, and so on.) We distill from these statements that $Q = 0$ when $I = \frac{1}{2}$ and that for $I \geq 1$, Q may be and usually is nonzero. The hexadecapole and higher existing moments have not been observed, probably because of their minute interaction energies. These conditions apply to all nuclei; however we enumerate them here because, since metals constitute over half of the Periodic Table, it is prudent as a first step for the experimentalist to ensure that a suitable isotope is available for any projected study. Usually tables list all relevant data.⁶ An additional useful fact is that the nuclear spin I is half integral

if the nuclear mass number is odd, and integral if its mass number is even.⁵

The above fundamental nuclear properties must be known if a metal is to be usefully probed. The observed magnetic dipole and electric quadrupole interaction energies are vector and tensor products, respectively, of the moments and the corresponding interaction parameters.

2 EXPERIMENTAL DETAILS

2.1 Specimen Preparation

Sample preparation is unquestionably one of the most important steps in any experimental study of metals or alloys. The metallurgical techniques necessary to prepare an alloy in a well-known state must be known and used. The characterization of metallic specimens after they are made is literally impossible. The only hope of understanding the NMR results is to have complete knowledge of the history of the alloy. The final step in preparation is usually reducing at least one and sometimes two or three dimensions of the sample to a size smaller than the skin-depth of the rf field in the specimen. At this point the metal is usually heavily cold worked and to some extent oxidized. A protective oxide layer may be very thin; a nonprotective oxide layer continues to grow if oxygen is present. The quantity of specimen in one powder particle of the total specimen is small (approx. 10–100 μg). The question of whether to anneal the specimen or not depends on having knowledge of the consequences of each alternative; there is no general answer and the choice depends upon the nuclear resonance and the materials aspects of the situation. Even the considerations involved are too numerous to introduce here. The nuclear spin, the annealing temperature of the metal or alloy, and the diffusivity of oxygen (or nitrogen, ...) at a proposed temperature are usually dominant factors.

The need to subdivide the metal was understood from the beginning; the *skin depth* or *depth of penetration* δ of the rf field into the metal depends on the frequency ν , and the resistivity ρ of the metal. The quantity δ plays a dual role in the experimental results; not only is it the distance into the metal at which the rf field strength falls to e^{-1} of its value at the surface, but a phase shift is introduced which mixes the absorption (imaginary or χ'') and dispersion (real or χ') components of the nuclear susceptibility χ .⁷ If the rf field does not penetrate the metal then it is the outer layer only (measured by δ) that contributes to the magnitude of χ . The *filling factor*, which is the ratio of the volume of sample in which the rf field energy is stored, to the total volume in which the rf field energy is stored, can also be greatly decreased. The ideal situation for nonspinning samples is to have the detector (receiver) coil just full of subdivided specimen, no particles of which are in electrical contact with any other and all of which are roughly of dimension $\delta \approx 5 \times 10^{-3}(\rho/\nu)^{1/2}$ where δ is in centimeters, ρ is in microhm centimeters, and ν is the frequency in megahertz.

The method of separation of the particles of specimen is chosen entirely on the basis of appropriateness. The temperature, state of the sample, and composition of sample often suggest materials such as mineral oil, any inert inorganic compound containing no active nuclei, e.g. Al_2O_3 when NMR

of V is observed, sheet mica, and so on. A minimum of 'filler' should be used to accomplish the particle separation; beyond that there is simply a loss of sample, filling factor, and signal.

The specimen may be either a pure metal or alloy. It is exceedingly difficult to handle metals of 99.9999% purity (usually called 'six 9s pure') or greater, without decreasing their purity. Fortunately the impurity is often on the surface only and it can be tolerated, or in some circumstances and with some risk, etched away. If during the preparation, a mechanical process such as filing, rolling, drawing, or swaging is used, the sample will be work hardened (cold worked) in addition to being contaminated. Work hardening is caused by mechanical imperfections in the lattice, primarily high densities of dislocations that comprise a three-dimensional 'forest'. The effects of mechanical and chemical imperfections will be discussed below.

2.2 Sample Containment and Conditions Used

Preparation of specimens for use at low temperature depends upon the detection technique being employed. Commonly a small thin-walled glass vial will be used to confine the specimen. For various reasons it is advisable to seal (tip off) the vial leaving the specimen under vacuum or an inert gas. Some of the same considerations apply to high-temperature NMR. A large number of experiments have been done on liquid metals.⁸ The separation of particles (spheres) and the choice of filler material is more difficult because of the likelihood of increased reactivity of sample with filler.

Finally it is interesting to note that many studies of the temperature dependence of the Knight shift were done in the solid state with the thought that the results would be approximations to volume-dependence measurements. Certainly the change in volume with temperature is a straightforward concept, but the intrinsic temperature dependence is less easily measured. The exact equation,

$$\left. \frac{\partial \ln K}{\partial T} \right|_p = \left(\frac{\partial \ln K}{\partial \ln V} \right)_T \left(\frac{\partial \ln V}{\partial T} \right)_p + \left. \frac{\partial \ln K}{\partial T} \right|_V \quad (1)$$

shows that obtaining the explicit temperature dependence of K on T at constant V requires use of the first term on the right, obtained from the pressure dependence of K at constant T and the compressibility $(\partial \ln V / \partial p)_T$, together with the coefficient of thermal expansion $(\partial \ln V / \partial T)_p$.⁹

2.3 Experimental Apparatus and Data

Early workers in the field usually used one of two or three types of nuclear resonance detection. A single-coil technique introduced by Pound¹⁰ was used almost exclusively by those working with or near him. Bloch used a cross-coil apparatus; students and others in his laboratory favored it. The 'Pound box' (a marginal oscillator) detected only the nuclear absorption χ'' , and was capable of sweeping over wide frequency regions with ease. The crossed coils, transmitter, and receiver, were constructed and adjusted in a way that made frequency change infeasible. An rf bridge technique was favored by many for its single coil capability and ease of use. For each method mentioned the rf field was applied

continuously so these were all used for steady-state NMR detection.¹¹ Audiofrequency modulation of the magnetic field B_0 and phase sensitive detection of the demodulated rf were commonly used to detect and display the derivative of χ'' or, for crossed coils, of a mixed χ'', χ' signal. For metals the separation of χ'' and χ' into pure components of χ is not straightforward. A bulk (1.27 cm $\times$ 1.9 cm) Al single crystal study illustrates the procedure under ideal circumstances.¹²

Pulsed nuclear resonance apparatus¹³ has proved to be almost universally superior to the steady-state methods. There remain pitfalls when the samples are metallic, and these are compounded if sample spinning is introduced. The skin effect and classical Eddy currents¹⁴ must be taken into account, or conversely, the sample prepared so as to make their effects negligible.

The data obtained from most magnetic resonance experiments eventually emerge in the form of absorption lineshape, width, amplitude (relative to a reference), and position (with respect to a reference). These are the quantities from which physical information, the goal of the work, is extracted. The interaction between the conduction electrons and the nuclei allows us to use the nuclear resonance as a probe of the charge density distribution. The association is not easy because of the complexity of the electron–nuclear, and electron–electron interactions; however problems with the theory are revealed as concepts of the electronic structure of the metal are refined. The number of locations in the lattice that can be probed are few, but when NMR is compared with other experimental approaches used to obtain data on this scale it has achieved a very impressive record.

2.4 NMR Lineshape in Powdered Metal Samples

In view of the fact that most NMR in metals is done on particles (or filings, foils, thin wires) with individual external dimensions of about 0.001" (0.0025 cm) it is clear that the sample comprises crystallites of at most that size or smaller. The results obtained from algebraic solutions of nuclear interactions are for single crystals and include the crystal orientation, as necessary, in keeping with the crystal symmetry. A number of such averaging calculations can be handled using no more than cylindrical symmetry and an average over all angles θ of the symmetry axis with respect to the magnetic field. This procedure is sufficient to treat hexagonal and tetragonal metal lattice structures as well as a large number of cubic, hexagonal, and tetragonal alloys. The absorption distribution $I(\nu)$ for an isotropic orientation distribution of crystals having axial symmetry is obtained by a transformation from crystallite orientation density to resonance amplitude at frequency ν ($B_0 = \text{constant}$). The calculation entails deriving $I(\nu)$ using $I(\nu) d\nu = \sin \theta d\theta$,¹⁵ and thus $I(\nu) \propto \sin \theta (\partial \nu / \partial \theta)^{-1}$. Derivations of NMR lineshapes (powder patterns) and the phenomena associated with structures of lower symmetry or causing low symmetry have been published.^{6,15}

2.5 Some Sources of Line Broadening in Stationary Samples

The implicit assumption has been made that the NMR resembles a Dirac δ function $\delta(\nu - \nu_0)$. There are at least three

sources of broadening in a stationary sample that contribute to the *linewidth* independently of its definition. The applied magnetic field is always inhomogeneous; the sample has nuclear dipoles and in the absence of atomic diffusion nuclear dipole–dipole interactions are a source of broadening; an internal field of totally classical origin is present because each metal particle has an internal field $B_{\text{int}} = \chi_m B_0$, where χ_m is the magnetic susceptibility of the metal. (This source can be significant in transition elements with large χ_m .) Lifetime or T_1 broadening is seldom a contributing factor to the linewidth of metals. T_1 and T_2 are the longitudinal and transverse relaxation times, respectively of the vector nuclear magnetization $\mathbf{M}$ in the stationary reference frame. M_z approaches its maximum equilibrium value in the direction of the external polarizing field; M_x and M_y decay toward zero through dephasing. These relaxation times appeared in Bloch's phenomenological equations describing the behavior of steady-state nuclear magnetization. The Bloch equations do not apply to solids in general, but the nomenclature has been carried over to the parallel quantities describing the behavior of $\mathbf{M}$. A brief, qualitative discussion of this topic appears in Schumacher.¹¹

3 PRINCIPAL THEORETICAL CONCEPTS

3.1 Introduction

The theory of NMR per se is presented in many books and papers. The interpretation of NMR in metals has been an especially active field because of the continuing interest in understanding the electron–electron interactions, which ultimately determine our understanding of the metallic state. Although high-temperature superconductors now attract much research (including NMR), for decades metals displayed properties and posed puzzles that were unique. Both type I and type II superconductivity and ferromagnetism have been thought to have their origin in the electron–electron and electron–phonon interactions in metals.

One of the tools that confirmed the Bardeen–Cooper–Schrieffer theory of superconductivity was NMR,⁶ and repeatedly it has shown its ability to reveal, on the atomic scale, electron distributions that cannot be otherwise obtained or can be obtained only with greater difficulty using another technique.

3.2 Electron–Nucleus Interactions

The topic of NMR in metals is one that can appear to lead to such complexity that it is intractable. Fortunately, however, all of the electron–nuclear interactions encountered can be formulated within the framework of quantum mechanics. It is helpful to understand the elements of the problem and the barriers to obtaining solutions in agreement with observation. Many of the difficulties can be identified in one statement: the potentials are not accurately known. The dense electron plasma is not completely understood; the chemical and other point imperfections (e.g. substitutional solutes, foreign atoms, vacancies and interstitial solutes) distort the lattice so that the positions of the surrounding atoms are not accurately known, and the potentials of the imperfections themselves are

perturbed self-consistently; higher dimensional imperfections such as dislocations (one-dimensional, 1D), grain boundaries, twin planes, and stacking faults (two-dimensional, 2D) are difficult to characterize in the metal and have received less attention than impurities and vacancies.

The above group of chemical and mechanical imperfections scatter conduction electrons and generate charge density fluctuations $\rho(\mathbf{r})$, which produce or perturb the following interactions: (a) hyperfine, (b) the electron–dipole nuclear–dipole, (c) indirect nuclear-spin exchange coupling via the conduction electrons, and (d) nuclear quadrupole. The magnitudes of the energy level shifts to which these give rise are usually related to the magnitudes of the nuclear dipole and/or electric quadrupole moments, and the external magnetic field. The derivation of all of the concepts to be included below and many more are explained in rigorous and elegant form by Slichter.¹⁴ A brief introduction to the application of NMR to pure metals and to alloys follows. Examples are offered of the way such studies are approached in terms of the information it is reasonable to expect. They are presented as models to help associate the atomic structure of a metal to the fundamental properties of a nucleus, which make it useful as a probe of that structure. Atomic structure includes lattice structure with imperfections and the total electronic structure. Nuclear properties include γ , I and Q as well as the mass and charge. Such quantities as isotopic abundance, and the bulk properties of the metal, both liquid and solid, are known.

3.3 Conduction Electrons and Scattering

The electronic structure of metals in its most exact form is responsible for the distinctive character of their NMR spectra. The electron energy levels of agglomerated metal atoms resemble those of any other solid when there is no overlap between wavefunctions, i.e. the inner levels are atomic in nature. The outer (conduction) electron orbitals of metals have significant overlap and the free atom energy levels are broadened into bands that may be 1–10 eV wide. Since each atom of a pure metal is identical to each other atom, and is neutral, no shift of charge from one atomic cell to another is expected. Rather, all conduction-electron wavefunctions are delocalized and exist over the volume of the bulk metal. For the alkali metals, which have highly s-like outer electrons; the valence bands are half-full. All metals in fact have only partially filled conduction (valence) bands and thus at $T = 0$ K have empty states within about 10^{-21} eV of the topmost filled energy level. Presentations of band theory (i.e. the energy distribution of electrons in solids and metals in particular) appear in the solid state literature.¹⁶ Of special interest are the transition metals in which s–d interactions are prominent; the s- and d-bands at the Fermi surface overlap and are partially full. Throughout the Periodic Table admixed orbitals can be expected for the conduction band. The greatest opportunity for systematic study is within the rows.

The s wavefunctions ψ_s play a crucial role in one of the useful applications of NMR in metals. The outer s radial wavefunctions $\psi_s(r)$ have the form $R_{n,s}(r) e^{-Zr/\sigma}$, where $R_{n,s}$ is a polynomial in r , n is the principle quantum number ($n \geq 1$), Z is the screened nuclear charge,¹⁷ r is the distance from the center of the nucleus, and σ is the screening radius. Since $\psi_s(r)$ is finite at the nucleus there is a magnetic interaction

between the nuclear magnetic dipole moment μ_I and the electrons in the metal. The magnetic field at the nucleus is $B = B_0 + \Delta B$, where B_0 is the field that would exist at the site of the nucleus in the absence of the metal (the ‘external’ or ‘applied’ field) and ΔB is the difference found by measuring $B - B_0$. The quantity of interest $\Delta B/B$ is known as the Knight shift K .² The quantity B_0 is usually obtained by using identical nuclei in an insulating diamagnetic solid, from a solution containing the isotope of interest, or the application of any other method by which it can be accurately measured. The medium used becomes the *reference*. The Fermi contact interaction in an atom has the form $E_a = a \mathbf{I} \cdot \mathbf{S}$ where a , the hyperfine coupling constant, is $(16\pi/3)\gamma_I\hbar\mu_B|\psi_s(0)|^2$. Here γ_I is the nuclear gyromagnetic ratio, μ_B is the Bohr magneton, and $|\psi_s(0)|^2$ is the outer s-electron concentration at the nucleus. In a simplified discussion⁴ it is found that $\Delta B = (a\chi_s M/g\mu_B\hbar\gamma_I)B_0$. A form more often used is

$$K = \Delta B/B = (8\pi/3)\chi_s\langle|\psi_A(0)|^2\rangle_{\text{FS}}M \quad (2)$$

where χ_s is the conduction-electron spin susceptibility per unit mass (also called the Pauli paramagnetism), M is the mass of the atom, and $\langle|\psi_A(0)|^2\rangle_{\text{FS}}$ is the probability density at the nucleus of the metal A atom of those electrons at the Fermi surface (FS) averaged over the FS. Earlier in this paragraph it was shown that $|\psi_s(0)|^2 \approx R_{n,s}^2(0)$. The Knight shift can, in principle, be used to measure the conduction-electron density for FS electrons at the nucleus, but the value of the s conduction-electron susceptibility χ_s is extremely difficult to measure accurately, and the experiment has been accomplished only rarely.¹⁸ The experimental determination of $\langle|\psi_A(0)|^2\rangle_{\text{FS}}$ and its comparison with calculated values is of fundamental interest; however, many applications of NMR to metals do not require knowledge of χ_s . There are experiments in which it can be made to ‘cancel out’ or in which relative differences in ΔB are important in themselves.

The conduction electron component χ_s of the magnetic susceptibility is assumed to be a bulk electronic property. According to equation (2) the Knight shift at the solvent lattice sites *around* an isolated solute atom at the origin will be different from the Knight shift K_0 of the pure solvent if the charge density is changed by the solute. The value of the quantity $\langle|\psi_A(0)|^2\rangle_{\text{FS}}$ is different in pure A than it is if a B atom is in a neighboring site. The perturbation caused by B of the charge density in A is effective over several lattice spacings and is spherical; consequently the n_i atoms in shell i at distance r_i from the B nucleus all experience the same change. The word ‘shell’ is used in the sense that the i th shell contains n_i atoms all at r_i . (Note that the solute atoms in a dilute alloy are often referred to as ‘impurity’ or ‘foreign’ atoms.)

The above physical description of a solute atom B located on a lattice site of the solvent A suggests treating the system from the point of view of scattering on an atomic scale. Conduction electrons with velocities ranging from near zero to the Fermi velocity v_F at the top of the band impinge on the B atom and are scattered by it. The scattering potential $V_B(r)$ can be computed using atomic wavefunctions, but a simple approach that demonstrates the effect is to use the spherical square well. Electrons in states below the Fermi surface cannot be scattered because all nearby momentum states are filled. Only electrons at the FS can be scattered: an integral of the scattered charge

over all states in the band shows that the only contribution is from electrons at the FS, and that the scattered electrons produce an oscillatory charge-density wave $\delta\rho(r_i)$ around the solute.¹⁹

The conduction-electron density at nuclei surrounding the scattering center is $\rho(r_i)$, the sum of ρ_0 ($\langle |\psi_A(0)|^2 \rangle_{\text{FS}}$ for the pure solvent) and the spherical wave $\delta\rho(r_i)$. An expression for $\delta\rho(r_i)$ is derived using the method of partial waves found in most standard texts on quantum mechanics.²⁰ Since $\delta\rho(r_i)$ is oscillatory and has a complicated dependence on r at short distances (several lattice spacings) expressions for it must be evaluated using the complete solution without simplification.²¹ An asymptotic approximation valid as $r \rightarrow \infty$ is $\delta\rho(r) \propto r^{-3} \cos(2k_F r + \theta)$, where θ is a function of the phase shifts η_l determined by the scattering potential. The asymptotic value for $\delta\rho(r)$ is never of use because: (a) even for a low solute concentration ($C_B \approx 0.01$) there is significant overlap among the charge density waves from the randomly distributed solutes and (b) the value of $\delta\rho(r)$ at large r is very small compared with other sources of linewidth. In summary, the effect of foreign atoms in a solvent matrix when the solvent nuclear spin I is $\frac{1}{2}$ is to cause a spectrum of resonance lines. Each line derives from the n_i solvent atoms in shell i . An example of such a study employing silver as the solvent and Group I, II, III, IV and V solute atoms demonstrated the presence of charge density waves.²²

4 PURE METALS WITH NONZERO μ_I

4.1 Initial Considerations: Lattice Symmetry and Nuclear Properties of Isotope(s)

The primary concern is the point symmetry at each lattice site, assuming an imperfection-free lattice. Of the 14 space lattices only three are cubic (yet these include many metals), four (trigonal, tetragonal and hcp) have three, four and sixfold axial symmetry respectively, and the balance have lower symmetry. There are thus three possible types of lattice symmetry to be combined with the nuclear and electron moments and the electron charge distribution; this is a closed set of possible combinations.

4.2 Pure Metals with $I = 1/2$

For nuclei of spin $I = \frac{1}{2}$ energy level changes are caused by the contact interaction and the nuclear–dipole electron–dipole interaction at a distance.^{15,23} The former has been discussed above (Section 3.3), the latter results from the non-s spin distribution in lattices with axial or lower symmetry. If for example a p_z orbital in a tetragonal lattice contained more charge than the $p_x = p_y$, then in the presence of a magnetic field the electrons near the top of the Fermi sea would produce a magnetic field at the nucleus with the axial symmetry of the spatial electron distribution. This *anisotropic Knight shift* has been observed in several metals with noncubic symmetry.⁶ The resulting powder pattern lineshape (because of the polycrystalline sample) is peaked by an integrable infinity at one end and falls off abruptly at the other, since the range of symmetry axis orientation (with respect to B_0) is from 0 to

180°, with the usual weighting factor of $\sin \theta$ for an isotropic orientation distribution. The number of crystallite orientations near $\theta = 90^\circ$ is infinitely greater than those near zero degrees. Since this anisotropy gives rise to a broadening mechanism proportional to the external field it is clearly linked to the electron polarization via the Pauli susceptibility; equation (3) gives the shift for a single crystal orientation θ ; it is

$$\frac{\Delta B}{B} = \mu_B^2 V_0 N(E_F) Q_K (3 \cos^2 \theta - 1) \quad (3)$$

where

$$Q_K = \int \psi (3 \cos^2 \theta - 1) r^{-3} \psi \, dV \quad (4)$$

The distribution of electron dipoles is contained in the conduction band wavefunctions ψ and the band structure determines $N(E_F)$. An s wavefunction would cause the integral to vanish so we have secondary evidence for the mixing of orbitals at the FS. Other factors important in pure metals with nuclei of $I = \frac{1}{2}$ are the *core polarization* (the polarization of inner s electrons simply because of the necessity of orthogonalizing all electrons in the atomic cell) and the *orbital* contribution.²³ The average value of the orbital magnetic moments is nonzero because currents are produced in the inner shells by the static magnetic field.

Another interaction depends upon the conduction-electron spins to couple nuclei. *Indirect coupling* describes the indirect spin–spin interaction between two nuclei i, j via the electron gas.²³ The wavefunction is in contact with both nuclei through their hyperfine interactions. This indirect exchange would be zero in the absence of s electrons; however it can be a dominant source of line broadening (and is expected to be if the hyperfine interaction is large). Large hyperfine interactions accompany large (massive) nuclei, and it is roughly true that the Knight shift and indirect nuclear coupling increase with increasing nuclear mass. The relationship is only approximate because of the many other contributing factors, not the least being the fraction of $\langle |\psi_A(0)|^2 \rangle_{\text{FS}}$, which is s-like.

Pure metals with $I = \frac{1}{2}$ but which are highly paramagnetic, may exhibit nuclear linewidths reflecting (i.e. increased by) the inhomogeneity δB_0 of the static field B_0 within the particle (unless the particles are all shaped and oriented so as to ensure that the demagnetizing factor is identical in each). The additional field is of the order of $\chi_m B_0$, where χ_m is the bulk measured volume magnetic susceptibility of the metal.⁶ A further contribution to the susceptibility, small in the simple metals but significant in transition metals, is the Van Vleck contribution χ_{VV} .²³ Shifts and linewidths found under the conditions of this section are of the order 0.1–1 mT.

4.3 Pure Metals with $I \geq 1$

The magnitudes of shifts and contributions to the absorption linewidth considered in Section 4.2 are likely to be totally overwhelmed by quadrupole splitting of the magnetic resonance if the lattice symmetry is other than cubic. The nuclear electric quadrupole moment Q is a measure of the shape of the nucleus and thus its charge distribution. Since magnetic resonance is the topic of interest we assume a high (1–10 T) magnetic field is present and the quadrupole perturbation is said

to take place in the high-field regime; the electric quadrupole interaction energy is much smaller than the nuclear magnetic dipole resonance energy $h\nu_0$. The magnitudes of the electric field gradient, the quadrupole moment, and $h\nu_0$ can vary over a sufficiently large range for both first- and second-order quadrupole perturbation to be frequently required in analyzing data. A comprehensive and authoritative monograph on this topic has been published.²⁴ In addition, the subject is covered in all works on NMR in metals and in the 'high-resolution' literature.²⁵ The information gained is interesting and useful, and there are more nuclei with $I \geq 1$ than with $I = \frac{1}{2}$ by almost a factor of 3. A concise yet moderately transparent expression for the quadrupole energy is the Hamiltonian,

$$\hat{H}_Q = \frac{1}{6} \sum_{j,k} V_{jk} Q_{jk} \quad (5)$$

The way in which the field gradients $V_{jk} = (\partial^2 V / \partial x_j \partial x_k)$ multiply the second rank tensor components Q_{jk} is reminiscent of other stress tensor-matter tensor interactions. The quantity Q , a scalar, is defined as the quadrupole moment of the nucleus, and is determined in the standard way of evaluating n -pole moments through knowledge of the charge distribution. By convention, the charge e is not included, and $Q = \frac{1}{2} \int (3z^2 - r^2) \rho(\mathbf{r}) d^3\mathbf{r}$, where $\rho(\mathbf{r})$ is the expectation value of the nuclear charge density for the state $m = I$. The expression requires knowledge of the probability density of the protons in the nucleus: Q is in fact a measured quantity, tabulated for many nuclei. (The accuracy to which Q is known is generally much lower than for the nuclear gyromagnetic ratio γ ; however, it should also be admitted that the reason nuclear scientists began to study shieldings, electron-nuclear interactions, and so on, was because they were a nuisance in accurately determining γ .) An extensive literature has developed in the pure metal, $I \geq 1$ subset;²⁶ there is opportunity for systematic study because so many transition and rare earth (f shell) metals are hcp.

Early in the work on quadrupole interactions it was pointed out by Sternheimer (cf. Ref.²⁴ p. 341) that a factor contributing to V_{ij} is $-\gamma_\infty V^*_{ij}$. The charge distribution of an atom is distorted by the quadrupolar field of its nucleus and by the electric field gradient caused by the other atoms in the lattice. Surrounding atomic cells appear to be ionic because the mobile charge tends to distribute uniformly over the lattice; the remaining ionic lattice should be summed to derive the $V^*_{ij} \rightarrow q_{\text{latt}}$ contribution to q from the lattice. The literature frequently uses a standard notation that incorporates these and other factors into the expression for the total field gradient q , given by

$$q = q_{\text{latt}}(1 - \gamma_\infty) + q_{\text{loc}}(1 - R_Q) \quad (6)$$

Here q_{latt} is discussed above, $-\gamma_\infty$ is the Sternheimer factor (which may be as large as 100 in heavy atoms) required to correct for the charge redistribution in the atoms caused by q_{latt} . The local field gradient from sources inside the atomic cell q_{loc} is also a sum of terms. Schumacher²⁷ provides a particularly good introductory treatment of the basic features of this topic.

4.4 Pure Metals with $I \geq 1$, and Mechanical Imperfections

The majority of the strain in a metallic lattice is the result of dislocations. An early experiment¹⁵ in which the resonance intensity of the untreated filings of Cu was compared with the intensity of annealed filings showed the effect of lattice distortion dramatically, since the satellite lines from the first order broadening were almost totally removed from the region of the central $I = \frac{1}{2} \rightarrow -\frac{1}{2}$ line; the intensity of the latter was decreased to about one-half of the absorption intensity in annealed Cu. A more careful analysis showed the slight narrowing of the Cu absorption line caused by the elimination of the contribution of the group of 'like' spins in regions of high lattice distortion. Dislocation pinning is very strongly dependent upon other imperfections, including grain boundaries and dislocations on other slip systems which cross the primary. When we use the concept of 'annealing temperature', for which there is a clear definition, the impurity content is the greatest unknown. By producing fine filings or heavily rolled or drawn Cu the dislocation density may be as high as 10^{12} cm^{-2} . This may be reduced to 10^6 – 10^8 cm^{-2} upon annealing. Even at 10^{12} cm^{-2} the majority of nuclei are not within several lattice spacings of a dislocation core.

5 ALLOYS

5.1 Solvent Nuclear Spin $I = 1/2$

5.1.1 Alloy Types and NMR

An alloy ordinarily is assumed to be any number of metals put into a perfectly inert container and melted under a vacuum or inert gas, then solidified under equilibrium conditions. The alloy specimens used for NMR should be very thoughtfully made; if called 'dilute' they usually consist of at most one or two elements present in minor concentration (0.1–10 at.%) in addition to the solvent. These are called binary or ternary alloys and may or may not be single phase.

Several compilations of phase (or equilibrium, or constitution) diagrams exist, and journals publish newly determined diagrams, updates, and extended work.²⁸ For elements and compounds of more than passing commercial or academic interest, individual monographs are devoted to the binary alloys of a single element. A four-volume work published by ASM characterizes intermetallic compounds, classifies them by structure type, and incorporates all dimensions and atom locations within the unit cell.²⁹ Similar collections of the literature of ternary alloys are available.

There are instances of the application of NMR to concentrated binary alloys with compositions ranging from 0 to 100 at.% B in an A–B alloy. Over this composition range, at room temperature, one can expect to encounter several solid solutions and/or intermetallic compounds with two phase regions separating them.⁶ The results obtained resemble those of an X-ray study of a binary system. It is seen, however, that X-ray diffraction studies are better in almost every way, when they are feasible. (For metals this means essentially always.) However, NMR is not a universal approach, but is useful

only for special felicitous choices of nuclei. Important factors include the spin and the magnitude of the dipole moment.

5.1.2 Solvent NMR in Dilute Substitutional Random Solid Solution (DSRSS)

This subject has been discussed above in the context of Section 3.3 for simple metal A–B alloys. The substitution of a paramagnetic species causes very long range spin density waves around the magnetic site acting as a scatterer.

5.1.3 Solute NMR in DSRSS

Many references have been made to the charge density waves scattered from a solute atom. If the solute B nucleus has spin $\frac{1}{2}$ it is possible (other conditions being favorable) that the solute resonance absorption will be observable. The B site is a center of symmetry, and it is possible to evaluate $\langle |\psi_s(0)|^2 \rangle_{B,FS}$ with the wavefunctions, theoretical techniques, and computing capabilities available.

5.2 Solvent Nuclear Spin $I \geq 1$

5.2.1 Solvent NMR in DSRSS

For DSRSS the scattering of electrons from solute atoms is unchanged from the foregoing description. Each impurity atom is imagined to be isolated and, by definition, on a site of the solvent crystal lattice. The solvent band structure and scattering process are unchanged. Here the similarity in treatment ends. Surrounding the solute are spherical charge density waves; these cause potential waves and electric field gradients that ripple out from the solute. Consider the $n_1 = 8$ nearest neighbors of a solute in a bcc lattice: Over the volume of a near neighbor (nn) cell the electric field changes and the quantity $V_{ij}^s(r_1)$ results at the nucleus. In addition, because of the presence of $V_{ij}^s(r_1)$, the electron orbitals in the nn cell are polarized. Crudely, this latter effect is the Sternheimer factor introduced earlier.

If the magnitude of V_{ij} at $r_1 = \sqrt{3}a_0/2$, where a_0 is the bcc lattice constant, is such that the quadrupole interaction energy, $\chi = e^2qQ/h$, is roughly equal to or within an order of magnitude greater than the unperturbed ($q = 0$) linewidth, a set of first-order satellite lines would in principle appear in the powder pattern of the NMR of the powdered DSRSS alloy.⁶ In practice, the distribution of both shifts and symmetries leads to a broad distribution of absorption at the solute concentrations used. A large number of measurements of q_i at several r_i have been done using more dilute solutions.

Because of the number of energy levels associated with the nuclear spin I , for integral I (i.e., $I = 1, 2, \dots$) there is no $m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition. For half-integral spin ($I = \frac{3}{2}, \frac{5}{2}, \dots$) the $m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$ transition is unperturbed and becomes the central $m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$ line of the first order quadrupole split line structure. Carter et al.⁶ illustrate the various patterns.

In second-order perturbation the remaining central ($m = \frac{1}{2} \leftrightarrow -\frac{1}{2}$) transition is shifted with respect to the unperturbed ($q = 0$) absorption. (Since first-order perturbation theory is no longer valid, but the higher $m \leftrightarrow m - 1$, $m \neq \frac{1}{2}$ transitions are very far removed, there are no longer observable satellites.)

The digression into high-field quadrupole perturbation was necessary to complete even a brief description of the many experiments in which q is the primary quantitative information obtained. A rather sweeping summation of the topic would state that in a large majority of DSRSS studies, the NMR absorption of an $I \geq 1$ solvent is either broadened, decreased in magnitude to an asymptotic limit, or decreased in magnitude to a very small value near zero. There is so little absorption left in the region of the original line that it can no longer be detected.

5.2.2 Solute Nuclei of $I \geq 1$ in DSRSS

Although many such studies exist, the principal interest in the results and the way in which the electronic structure interacts with the nuclei have been described. A study that involves the combined effects of nuclear quadrupole interaction, anisotropic Knight shift, dipolar broadening, and an inhomogeneous Knight shift distribution at the solute sites,³⁰ can serve as an example of a more complex system; the solutes Al and V were dissolved in hcp Ti in concentrations of 1 at.% and 2 at.%. A semiquantitative analysis of the Ti lattice wavefunction as it joins the localized orbitals in the Al and V cells is carried out. The substitution of Al on an hcp Ti site decreases the Knight shift of Al to near zero. The $3s^2$ orbitals probably lie below the Fermi surface of Ti.

5.2.3 Further Considerations

Very large segments of material have been omitted from this entry. Each is as significant as the material included, and the choice of topics presented is merely slanted toward the most basic considerations of nuclear interaction and the simplest aspects of metals and alloys, stressing their electronic structure in real space. It is clear that other electronic properties are very closely related to this area. For example, the electronic specific heat is directly proportional to $N(E_F)$, a factor in $(\Delta B/B)$. The residual resistivity (that part related to solutes in DSRSS) involves electron scattering processes, one aspect of which invokes the same phase shifts as appear in the evaluation of the solvent Knight shift in DSRSS using the method of partial waves.

6 NUCLEAR RELAXATION AND ATOMIC DIFFUSION: NUCLEAR RELAXATION IN $I = 1/2$ SYSTEMS

The discoverers of NMR worried about this topic. It is easy to see that in order to absorb net energy, a spin in a lower level must be excited into an upper level. How long can this go on? Experience shows that if the incoming photon density is not too large, it can go on forever, but if the magnitude goes beyond some critical level, the net photon absorption decreases, the populations of the upper and lower level approach equality and net absorption approaches zero. The strong implication is that there exists a mechanism by which nuclei in the upper energy state return to the lower state and lose the required energy to the lattice, a passing electron, a paramagnetic impurity, or by another process that can absorb the required energy $h\nu_0$. The spontaneous loss of energy to a large reservoir is described by

the relaxation time T_1 . In metals T_1 is determined most often by collisions with passing conduction electrons; the calculation of T_1 was done by Korringa who found that the temperature $\times T_1$ product is a constant in this case. Since nuclei relax via the contact interaction, T_1 is found to be directly related to the Knight shift.²³

Another type of relaxation occurs because of the static dipole–dipole interactions among the nuclei. The transverse dipolar relaxation time T_2'' is calculated from the nuclear moments and their lattice locations in terms of the second moment of the dipolar field.³¹ (If all lattice sites are occupied by nuclei with magnetic dipole moments then a field caused by all of the other dipoles is present at each site.) If the nuclei move through the lattice the average field at any nucleus will decrease and the more rapid the motion the narrower the resonance line. Accurate measurement of the linewidth as a function of temperature measures the activation energy of diffusion for this motional narrowing.¹⁴ The mean time between atomic jumps has also been measured for Al using a pulse technique.³²

1 INTRODUCTION

The geometric phase of a quantum system is that portion of its total phase that is independent of the details of the system's temporal evolution. Thus, consider a quantum system prepared in an eigenstate $|\phi\rangle$ with energy E . The evolution of this system is just the familiar $\exp(-iEt/\hbar)|\phi\rangle$. The phase of the eigenstate, $-Et/\hbar$, is purely dynamic because it depends on the length of time t for which the system has evolved. It turns out, perhaps surprisingly, that in systems with sufficiently complex geometry there is an additional contribution to the total phase that is independent of time, but that does depend on the shape of the space through which the system evolves. This component of phase is thus termed geometric. As we illustrate below, even as simple a system as a spin in a moving magnetic field can acquire a geometric phase. Nevertheless, the existence of this effect was largely overlooked until Berry's seminal paper,¹ with some notable exceptions.^{2,3} The history of the geometric phase has been outlined by Berry.⁴ Since the publication of Berry's initial paper,¹ a wealth of primary and secondary literature has appeared (see, for example, Shapere and Wilczek⁵ and Zwanziger et al.,⁶ and references therein).

The geometric phase is a general phenomenon, and has been shown to be significant in a wide range of applications.^{5,6} The exquisite control that magnetic resonance experiments can achieve has proven crucial in providing unambiguous tests of its existence and geometric properties.⁷⁻¹⁰ Moreover, its description has stimulated a new way of thinking about a variety of NMR experiments that has led to the prediction of new phenomena.⁸⁻¹¹ Below we will briefly outline both the general theory of geometric phases, and NMR experiments that have verified the theory.

2 THE GEOMETRY OF QUANTUM EVOLUTION

2.1 The Aharonov–Anandan Phase

The geometric treatment of the general case of quantum evolution is due to Aharonov and Anandan,¹² and we follow their discussion here. Consider, for simplicity, a two-level system, assumed to be in a pure state. The state is completely characterized by its density operator $\hat{\rho}$, which is Hermitian ($\hat{\rho}^\dagger = \hat{\rho}$), idempotent ($\hat{\rho}^2 = \hat{\rho}$), and normalized such that it

has unit trace. The set of all such operators spans a two-dimensional space that has the geometry of a sphere. The evolution of the two-level system can be viewed as a path on this sphere. We associate a wavefunction $|\psi\rangle$ with each density operator in this space, through $\hat{\rho} = |\psi\rangle\langle\psi|$; in fact, we can associate an infinite set of wavefunctions with each $\hat{\rho}$, since the overall phase of the wavefunction is irrelevant. Now suppose that the system is prepared initially in the state $|\psi(0)\rangle$, and that the system evolves along some closed path in the space of density operators during a time T . The system must return to its initial state, up to a phase, as shown in equation (1).

$$|\psi(T)\rangle = e^{i\alpha}|\psi(0)\rangle \quad (1)$$

In general, the phase α includes contributions from both the dynamic and geometric phases. Using $|\psi\rangle$, we define the ket $|\tilde{\psi}\rangle$ through equation (2).

$$|\tilde{\psi}(t)\rangle = e^{-i\phi(t)}|\psi(t)\rangle \quad (2)$$

Here ϕ is determined by the condition in equation (3)

$$\phi(T) - \phi(0) = \alpha \quad (3)$$

The reason for making this definition is that we have obtained a ket such that $|\tilde{\psi}(T)\rangle = |\tilde{\psi}(0)\rangle$. The original state $|\psi(t)\rangle$ obeys the Schrödinger equation

$$i\hbar \frac{d|\psi(t)\rangle}{dt} = \hat{\mathcal{H}}(t)|\psi(t)\rangle \quad (4)$$

where $\hat{\mathcal{H}}(t)$ is the Hamiltonian of the system. By substituting the definition of $|\tilde{\psi}\rangle$ into equation (4), a differential equation for $\phi(t)$ can be obtained:

$$-\frac{d\phi(t)}{dt} = \frac{1}{\hbar} \langle\psi(t)|\hat{\mathcal{H}}(t)|\psi(t)\rangle - \langle\tilde{\psi}(t)|i\frac{d}{dt}|\tilde{\psi}(t)\rangle \quad (5)$$

Integrating equation (5) shows that the total phase acquired by the system can be expressed in two parts. One part is dynamic, in the sense of depending in detail on the Hamiltonian, and is given in equation (6).

$$\alpha_D = \frac{1}{\hbar} \int_0^T \langle\psi(t)|\hat{\mathcal{H}}(t)|\psi(t)\rangle dt \quad (6)$$

The other portion of the phase is given in equation (7).

$$\gamma = \int_0^T \langle\tilde{\psi}(t)|i\frac{d}{dt}|\tilde{\psi}(t)\rangle dt \quad (7)$$

The phase γ is independent of the Hamiltonian, and in fact depends only on the path through the space of $\hat{\rho}$, and not at all on the mechanism that forces the system to traverse that particular path. Note that γ depends on $|\tilde{\psi}(t)\rangle$, not $|\psi(t)\rangle$. The functions $|\tilde{\psi}(t)\rangle$ were explicitly constructed to be free of phase factors, and so we can be sure that a phase generated by integrating the form $i\langle\tilde{\psi}(t)|d/dt|\tilde{\psi}(t)\rangle$ is free of trivial (in the present context) contributions from energy factors and so forth.

Having derived a component of the overall phase of the system that depends only on the geometry and not the Hamiltonian, we can ask under what conditions this term is nonzero. Of particular interest is equation (7), evaluated along a closed loop in the space of density operators. Recognizing that the time t merely parameterizes the path (call the path C), we can rewrite the integral in terms of the path itself, as shown in equation (8).

$$\gamma(C) = i \oint_C \langle \tilde{\psi} | d | \tilde{\psi} \rangle \quad (8)$$

The phase $\gamma(C)$ is often called the Aharonov–Anandan phase (AA phase). Now at any given point on the path one could pick kets such that the integrand of equation (8) is zero there (this is probably why the geometric phase was overlooked for so long). But what is important is the integral around a finite path; it turns out that for spaces that are curved, such as spheres, or spaces with holes, such as the punctured plane, it is impossible to pick kets for which the integrand is *globally* zero. Then $\gamma(C)$ is, in general, nonzero. In NMR the experimentally relevant case is a spherical geometry, this being the shape of the space of density operators of a two-level system. The phase $\gamma(C)$ can be evaluated exactly in this case, yielding the beautifully compact formula shown in equation (9).

$$\gamma(C) = m\Omega(C) \quad (9)$$

Here m is the magnetic quantum number of the state being propagated, and $\Omega(C)$ is the solid angle subtended at the origin of the sphere by the path C . Examples of the geometric phase for different paths are shown in Figure 1.

2.2 The Adiabatic Limit: The Berry Phase

The AA phase described above arises from the geometry of the space of density operators; its generality is due to its independence of the details of the Hamiltonian associated with a given system. The discovery of the AA phase was actually preceded by the discovery by Berry of a geometric phase associated with adiabatic evolution;¹ this so-called Berry phase is a special case of the AA phase. The Berry phase arises from the geometry of the set of Hamiltonians associated with the slowly changing system; we sketch its derivation in this section.

Figure 1 Paths in the space of density operators of a two-level system. The solid angle subtended at the origin is $2\pi(1 - \cos \theta)$ for the cone, θ for the triangle, and 2θ for the slice. (Reproduced by permission of the American Physical Society, from D. Suter, K. T. Mueller, and A. Pines, *Phys. Rev. Lett.*, 1988, **60**, 1218)

The calculation of the Berry phase begins by considering a Hamiltonian that depends on some set of parameters $\mathbf{R}$; for any given set $\mathbf{R}$ we solve the associated Schrödinger equation to find the energies and states of the system, conventionally indexed by the quantum number n , as shown in equation (10).

$$\hat{\mathcal{H}}(\mathbf{R})|n(\mathbf{R})\rangle = E_n(\mathbf{R})|n(\mathbf{R})\rangle \quad (10)$$

The time dependence of the problem is due to the time dependence of the parameters. If the Hamiltonian that drives the system varies slowly in time, compared with the natural precession period of the system, then the evolution can be accurately described in the adiabatic approximation.¹³ In the adiabatic approximation, the state of the system at time t is

$$|\psi(t)\rangle = e^{i\gamma} e^{-i \int_0^t E_n[\mathbf{R}(t')] dt' / \hbar} |n[\mathbf{R}(t)]\rangle \quad (11)$$

Here it is assumed that $|\psi(0)\rangle = |n[\mathbf{R}(0)]\rangle$. A differential equation for the phase γ can be obtained by using $|\psi(t)\rangle$ in the time-dependent Schrödinger equation, and acting with $\langle n(\mathbf{R})|$ on the left. The (integrated) result is summarized in equations (12) and (13).

$$\gamma = i \int_0^T \langle n(\mathbf{R}) | \frac{d}{dt} | n(\mathbf{R}) \rangle dt \quad (12)$$

$$= i \oint_C \langle n(\mathbf{R}) | \nabla_{\mathbf{R}} | n(\mathbf{R}) \rangle d\mathbf{R} \quad (13)$$

This phase is a special case of equation (8) above; we need merely to identify $|n(\mathbf{R})\rangle$ in the present case with $|\tilde{\psi}\rangle$. The natural interpretation is slightly different between the two cases; whereas we interpret the AA phase as arising from the geometry of the space of density operators, the Berry phase, equation (13), arises from the geometry of the parameter space as determined by the set $\mathbf{R}$.

A simple example of a nonzero Berry phase arises for a spin- J particle in a magnetic field of constant magnitude and time-dependent direction. The parameter space $\mathbf{R}$, here just the three components of the magnetic field, has again the geometry of a sphere. If the rate of change of the direction of the field is small compared with the precession rate of the spin around the field, then the adiabatic treatment outlined above holds, and we can expect the Berry phase shown in equation (14).

$$\gamma_n(C) = n\Omega(C) \quad (14)$$

This result is analogous to equation (9) above. This example appears in Berry's original paper,¹ and in more detail in the book by Bohm;¹⁴ a rotating frame analog has been studied experimentally by Suter et al., and equation (14) verified.¹⁵

Although the Berry phase is a special case of the AA phase, more applications in NMR have made use of it, probably because the language describing it is somewhat more familiar. As noted above, whereas the AA phase arises from paths in density operator space, the Berry phase is best viewed as arising from the path followed by the Hamiltonian itself, or, more to the point, of the quantization axis of the system. A slowly varying quantization axis should always be suspected of giving rise to a Berry phase, which in many cases of interest is fairly simple to compute. The simplicity arises from the spherical geometry of the standard parameter space. For the

AA phase, however, while the two-level system yields a simple result, generalization to even a three-level system becomes significantly more complex.¹⁶ The experimental examples of these phases to be discussed below also highlight the subtly different ways they affect real measurements.

3 EXPERIMENTAL CONSEQUENCES OF GEOMETRIC PHASES

3.1 Measurement of the Aharonov–Anandan Phase

A thorough investigation of the phase $\gamma(C)$ [equation (8)] has been carried out by Suter, Mueller, and Pines.⁷ The primary obstacle that any experimental study of such a phase must overcome is that global phases associated with the density operator of an *isolated* system are in principle immeasurable. To see this, recall the invariance of $\hat{\rho}$ to phase changes; the density operator conveys all the information about the system, and the global phase is irrelevant. To measure the phase it is necessary to couple the system to its environment; since this is precisely what is done in any experiment, we see that phase shifts, even of density operators, can be expected to be important not only in theory but in practice as well.

The maximum amount of information about the phase of a system coupled to an environment is provided by an interferometric experiment, and this was the strategy pursued by Suter et al.⁷ Using an approach similar to that employed by Vaughan and colleagues in a study of spinor behavior,¹⁷ a pair of levels in a three-level system was used to provide the two-level density operator to be manipulated. Coherence to the third level provided the phase reference.

Call the phase reference level one and the two-level subsystem levels two and three. The experiment proceeds by applying a selective $\pi/2$ pulse to the 1–2 transition, producing coherence. A time τ later a π pulse is applied to these levels, which will generate an echo. The phase of this echo provides the phase reference; it also has the advantage of refocusing all the dynamic evolution during the time τ . In a second experiment, during the refocusing period pulses are applied to the 2–3 subsystem to drive the associated density operator through a cycle such as those shown in Figure 1. Because this subsystem has a level in common with the 1–2 transition, the phase of the refocused 1–2 coherence is sensitive to the phase of the 2–3 state. In the work of Suter et al.,⁷ this sequence was carried out for a variety of paths C of the 2–3 subsystem, and the phase of the 1–2 echo measured. The predicted phase shifts of these experiments are $\frac{1}{2}\Omega(C)$ [see equation (9)]; the experimental results and the theory are given in Figure 2. These results show that the phase $\gamma(C)$ does indeed depend on the solid angle in the way predicted; this experiment represents a complete and thorough test of the geometric evolution predicted in equation (8).

3.2 Measurement of the Berry Phase

Because any adiabatic reorientation of the quantization axis of a system can yield a geometric phase, there are a number of examples from NMR of this kind of geometric evolution. The most commonly occurring case is in solid state NMR at

Figure 2 Experimentally determined values of $\gamma(C)$ as a function of solid angle $\Omega(C)$. The paths used are those shown in Figure 1. The solid line is theory [equation 9]. (Reproduced by permission of the American Physical Society, from D. Suter, K. T. Mueller, and A. Pines, *Phys. Rev. Lett.*, 1988, **60**, 1218)

intermediate to low fields, where the spin degrees of freedom of the nuclei are not completely decoupled from the spatial degrees of freedom. In such a case, sample reorientations (for example, rotation) yield a slowly changing quantization axis, and hence a geometric phase.^{8,9,11} The experiment of Tycko⁸ is a particularly vivid example of this behavior.

Tycko performed a pure nuclear quadrupole resonance (NQR) experiment on the ^{35}Cl nuclei in a rotating single crystal of sodium chlorate (NaClO_3). In this material the quadrupolar interaction is dominant for the chlorine spins, yielding a transition frequency (in zero field) of some 30 MHz. The quantization axis for the chlorine is determined by the quadrupole principal axis system (PAS). By placing a single crystal of NaClO_3 in the tuned NQR detection coil, with the crystal c axis collinear with the coil axis, all four chlorine nuclei in the unit cell have equivalent orientations because the principal axis of each is at an angle of 54.74° with respect to the coil axis, and the quadrupolar interaction is axially symmetric ($\eta = 0$). Such an orientation, like any other, gives a single sharp NQR line. When the sample is made to rotate, however, the spectrum changes qualitatively. Rotating around the crystal c axis preserves the equivalence of the chlorine nuclei in the unit cell, but now the quantization axis of each one is time-dependent, tracing a circle around the coil axis (Figure 3).

Each spin state $|n\rangle$ acquires a geometric phase γ_n [see equation (13)] at a constant rate, and since the coupled partners in observable transitions ($|\frac{3}{2}\rangle \leftrightarrow |\frac{1}{2}\rangle$ and $|\frac{1}{2}\rangle \leftrightarrow |-\frac{1}{2}\rangle$) pick up different phases, shifts of the resonance lines are observed in the spectrum. There is a subtlety in defining the spin states due to their degeneracy in zero field;^{8,18,19} suffice it to say that the $|\pm\frac{3}{2}\rangle$ pair are unmixed by the rotation, and so yield good basis states, and that the superposition of the $|\pm\frac{1}{2}\rangle$ states with mixing angle $\arctan(2 \tan \theta)$, with θ being the angle between the quadrupole PAS and the coil axis, form good basis states. These states can be used in equation (13) to calculate the phase shift. The phase differences, modulo 2π , for the observable transitions are 0 and $\pm 2\sqrt{3}\pi$, which translate, in the frequency

Figure 3 The experimental arrangement used in the pure NQR experiment of Tycko. The crystal c axis of NaClO_3 is oriented along the coil axis; the sample can be rotated around this axis. (Reproduced by permission of the American Physical Society, from R. Tycko, *Phys. Rev. Lett.*, 1987, **58**, 2281)

domain, into shifts at 0 and $\pm\sqrt{3}\omega_R/2\pi$ Hz (with $\omega_R/2\pi$ the rotation frequency). Note the difference between this result and the usual spinning sidebands of high field solid state NMR: here there are always four lines of constant relative intensity (two are degenerate at zero frequency shift) for all rotation speeds, and the splittings are irrationally related to the rotation frequency. Spectra, at different rotation frequencies, are shown in Figure 4. This very clean result clearly demonstrates the Berry phase, and also illustrates the primary regime in which geometric phases are important in NMR: intermediate to low field experiments, in which the quantization axis is time-dependent.

4 SUMMARY

While geometric methods have been important in relativistic quantum mechanics for some time, it is only recently that they have become used in the nonrelativistic case. The geometric phases discussed here are concrete realizations of the importance of geometry in even simple systems such as spins in magnetic fields. NMR has played a major role in demonstrating their properties, and in turn, geometric approaches are providing new insights and new predictive power into the design of magnetic resonance experiments.

1 INTRODUCTION

Molten salts represent an interesting class of liquids possessing unique ionic interactions. In this type of liquid, the usual ion–solvent forces are replaced by ion–ion interactions and possess Lewis acid–base properties. Molten salts may be classified according to either composition and/or temperature range: (1) high temperature molten salts which generally contain only inorganic salts, and (2) room temperature molten salts which contain both organic and inorganic components. There are numerous excellent books and reviews of molten salt chemistry, however only a few contain references to NMR studies of these highly ionic liquids.^{1–5}

NMR studies of high-temperature molten salts often require special equipment (high-temperature probes, etc.), as described in a recent review article.³ Room temperature molten salts need special treatment only in the preparation of the sample itself (usually in a drybox, followed by sealing with a torch immediately after removing the sample from the drybox). Both types of molten salt have been used as the subject of basic studies by NMR over a wide range of nuclei including ¹H, ²H, ⁷Li, ¹³C, ¹⁷O, ¹⁹F, ²³Na, ²⁷Al, ³⁹K, ⁸¹Br, ⁸⁷Rb, ¹²⁷I, and ²⁰⁵Tl.

2 MICRODYNAMICS

2.1 Spin State Population

The distribution of nuclear spin states is affected by the application of low intensity radiation, resulting in a net absorption of energy and a redistribution of spin states. Removal of the source of radiation results in a return (relaxation) of the excited nuclei to ground state conditions. The rate of this relaxation process in the liquid state is controlled by rapidly fluctuating magnetic fields associated with rotational and translational motion. Theoretical models typically describe relaxation processes in terms of either rotational and/or translational correlation times. The correlation time τ_c typically represents the time taken by the involved nuclei to rotate, translate or be involved in such events as phase changes (see *Brownian Motion and Correlation Times*).

2.2 Relaxation and Correlation Times

Relaxation times are designated as either spin–lattice (T_1) or spin–spin (T_2), depending upon the type of interaction and the method used to obtain them. Relaxation rates are simply the inversion of relaxation times ($R = 1/T$). Spin–lattice (longitudinal) relaxation times (T_1) are obtained by the inversion–recovery method and spin–spin (transverse) relaxation times are obtained from either linewidth ($T_2^* \approx T_2$) or spin echo (T_2) measurements (see *Relaxation: An Introduction*). The theoretical equations that define relaxation times (rates) as a function of correlation time are relatively simple in the ‘extreme narrowing region’ where $\omega\tau_c \ll 1$ ($\omega = 2\pi\nu$). At low temperatures (approaching the solid or glassy state) where $\omega\tau_c \approx 1$, the equations become increasingly complex. In this region (T_1 minimum), one can still solve the correlation equations by assuming that $\omega\tau_c = 1$.

2.3 Relaxation Mechanisms

Relaxation studies of molten salts provide an excellent source of structural information which is difficult or impossible to obtain by other physical methods. Much useful information can be obtained from knowledge of spin–lattice (longitudinal) and/or spin–spin (transverse) relaxation times (see *Relaxation Processes: Cross Correlation and Interference Terms*). The relaxation mechanisms that may be observed include dipolar, quadrupolar, spin–rotation, chemical shift anisotropy, scalar, and paramagnetic (see *Relaxation Theory for Quadrupolar Nuclei* and *Carbon-13 Relaxation Measurements: Organic Chemistry Applications*). Of these mechanisms, paramagnetic relaxation is often the most effective. Consequently, one must be careful to exclude paramagnetic impurities from the melts under observation.

2.4 Relaxation Studies

The first significant papers on molten salt relaxation studies dealt with ¹H linewidth studies of potassium stearate.^{6,7} These early investigations demonstrate the usefulness of this technique by correlating large changes in R_2 ($= 1/T_2$) with phase transitions. A recent ¹H relaxation study⁸ of the *N*-(1-butyl)pyridinium chloride–aluminum chloride system compares intramolecular rotational correlation times with melt viscosities. The data obtained in the acidic melt⁸ region (AlCl₃ in excess) where Al₂Cl₇[−] is present, indicates that the extreme narrowing condition ($\omega\tau \ll 1$) is not met in these highly viscous melts. In the basic or neutral melts, where AlCl₄[−] is the primary anionic species, the extreme narrowing condition is apparently upheld.

In the initial studies of group I cations in high temperature molten salts^{9,10} the spin–lattice relaxation times (T_1) of ²³Na and ⁷Li in molten NaNO₃ and LiNO₃/KNO₃ mixtures are reported and the relationships between quadrupolar relaxation, diffusion and ionic radii carefully analyzed (see *Relaxation Theory for Quadrupolar Nuclei*). The conclusion¹⁰ that long-range order in the melt no longer exists as it does in the solid is supported by the fact that the largest part of the electric field gradient comes from only one neighboring anion and, therefore, models of ionic interactions in the melt should

involve only nearest neighbors. It should be pointed out, however, that the author¹⁰ assumes that ^7Li relaxes by a purely quadrupolar relaxation mechanism, although it is likely that dipolar effects are also present as is often the case for ^7Li relaxation.

This type of high-temperature study is extended¹¹ to ^{23}Na and ^{87}Rb in molten NaNO_3 and RbNO_3 . The authors¹¹ calculate field gradients around the cations using results from X-ray diffraction studies to test various models and conclude that relaxation processes from translational motion are more important than those from rotational motion. In a following report, they¹² study the relaxation of ^{81}Br and ^{127}I in molten LiBr and LiI . As is often the case, the NMR relaxation correlation times¹² differ by several orders of magnitude from those obtained from viscosity measurements of the same systems.

Chloroaluminate room temperature melts have been the focus of a number of relaxation studies (^1H , ^{13}C , ^{23}Na , and ^{27}Al).^{8, 13–16} Attempts by investigators^{8, 13} using viscosity to calculate correlation times from

$$\tau_c = \eta V / kT = 4\pi a^3 \eta / 3kT \quad (1)$$

and to determine adequately molecular size from this equation have generally been unsuccessful. The correlation times determined from viscosity are typically two orders of magnitude larger than those determined from NMR.⁸ Use of equation (1) to calculate ionic radii a from NMR correlation times also provides unrealistic values. The use of the Stokes–Einstein equation

$$D = kT / 6\pi \eta a \quad (2)$$

with diffusion coefficients to obtain complex radii is more promising.¹³

Another use of relaxation measurements involves the dual spin probe (DSP) method.^{14, 15} The DSP method requires that neighboring nuclei form a chemical bond or complex, which implies that these nuclei undergo simultaneous rotation and therefore have the same correlation time (assuming that a rotational model is appropriate). In the case of ^{13}C and ^{27}Al , this leads to approximate equality between the ^{13}C dipolar correlation time τ_{eff} and the ^{27}Al quadrupolar correlation time τ_Q :

$$R_1^{\text{dipolar}}(^{13}\text{C}) = N_H (\hbar \gamma_C \gamma_H)^2 r_{\text{CH}}^{-6} \tau_{\text{eff}} \quad (3)$$

$$R_1^Q = [(3/10)\pi^2(2I + 3)/I^2(2I - 1)][1 + (z^2/3)]\chi^2 \tau_Q \quad (4)$$

$$\chi [e^2 Q q / h] = \text{QCC} \quad (5)$$

The DSP assumptions include: (1) the asymmetry factor z is zero; (2) the intramolecular dipolar relaxation model (^{13}C) is adequate; and (3) the system is within the boundary of the extreme narrowing condition ($\omega\tau < 1$). If all these conditions are met, a plot of $R_1^{\text{dipolar}}(^{13}\text{C})$ versus R_1^Q will be linear and pass through the origin.^{14, 15} An important result of this analysis is that it provides a method for determining quadrupolar coupling constants (QCCs) in the liquid state.^{14, 15}

An alternative method for determining QCC values is to lower the melt temperature until a T_1 minimum is observed. At

this point, $\omega\tau_c \approx 1$ and the correlation equation can be solved exactly.¹⁶ This same approach can be used in all melts for ^{13}C , ^1H , and other nuclei. Solution of the correlation equations is readily accomplished using a desktop computer system.

3 CHEMICAL SHIFTS

3.1 Physical Interpretation

Chemical shift studies^{17, 18} of a series of molten thallium salts are able to relate the ^{205}Tl chemical shift to the square of the overlap integral giving a measure of the degree of covalency. In these studies, ^{205}Tl chemical shifts in Tl(I) and Tl(III) salts are reported relative to TlNO_3 as a function of temperature. The observation that TlCl_3 has a large chemical shift relative to TlNO_3 and that it undergoes a very small change upon melting leads to the conclusion that the Tl(III) atoms are deshielded by the chlorine atoms within the molecule and yet are strongly shielded from neighboring molecules within the melt. The authors^{17, 18} also conclude that Coulombic forces predominate in molten halides while in covalent species (AlCl_3) intermediate forces such as ionic, covalent, dipolar, and van der Waals forces must play roles of varying importance.

3.2 Equilibrium Constants

Chemical shift values are often used to calculate equilibrium constants of molecular and ionic complexes. The basic assumption is that the observed chemical shift is the sum of the concentration-weighted chemical shifts of the free and complexed nuclei. One can usually solve these equations using either mole fraction or molar concentration terms. The resulting information is extremely useful and relatively easy to interpret compared with attempts to analyze chemical shifts of individual species which, by definition, contain a number of complex terms (see *Shielding Calculations: LORG and SOLO Approaches*).^{17, 18} The following is a typical derivation¹⁹ of the equations necessary for equilibrium analysis given the system, $A + B \rightleftharpoons C$, where (a) $B > A$, (b) one assumes that A and C have characteristic chemical shifts δ_A and δ_C , and (c) the observed chemical shift δ_{obs} is the weighted arithmetic mean of δ_A and δ_C :

$$K = C / B_0 (A_0 - C) \quad (6)$$

$$\delta_{\text{obs}} = [C / A_0] \delta_C + [(A_0 - C) / A_0] \delta_A \quad (7)$$

If we let $\Delta = \delta_{\text{obs}} - \delta_A$ and $\Delta_0 = \delta_C - \delta_A$, then

$$\Delta / B_0 = -K (\Delta - \Delta_0) \quad (8)$$

The major advantage of equation (8) is that a plot of Δ / B_0 versus Δ will give a straight line with a slope equal to $-K$ and an intercept of $K \Delta_0$. This avoids the inherent errors produced from a plot that gives the equilibrium constant as the reciprocal of the intercept (this often results in $1/K$ values close to the origin, producing a considerable error in the value of K). There still remains, however, the problem of determining δ_A .

In molten salts, it may be necessary to plot δ_A (observed) versus $1/A$ and extrapolate to the y intercept ($A = \infty$) by the use of a polynomial fit to obtain a value of $\delta_A(\text{free})$. Iterative methods can also be used to solve equations (6)–(8).

Examples of equilibrium constant determination include studies of tetrachloroaluminate melts^{20–22} in which the cationic source is either 1-ethyl-3-methylimidazolium chloride^{20,22} or *n*-butylpyridinium chloride.²¹ The first of these studies²⁰ used ^{13}C NMR chemical shifts to establish which anionic species were present as a function of melt composition. The second study²¹ identified and analyzed the equilibrium between LiCl_2^- and the LiCl_2^- dimer using ^7Li NMR. The last report²² examined the equilibrium between HCl , Cl^- , and HCl_2^-

using ^2H NMR and provides an excellent example of the use of the iterative method.

3.3 Contaminant Species

A problem that always exists in molten salt studies is the possible presence of water (and similar contaminants) resulting in the formation of various oxides. The presence of these impurities have led to several honest misinterpretations of NMR spectra in the literature. An important ^{17}O NMR study of chloroaluminate melts containing water has analyzed this problem in careful detail.²³

4 CHEMICAL EXCHANGE

4.1 Categories of Molecular Events Based on Rate of Occurrence

These categories include: (a) equilibrium species whose interconversion is slow relative to the NMR timescale, thus providing specific chemical shifts for each species; (b) species whose interconversion is extremely rapid relative to the NMR timescale, resulting in an average chemical shift which includes all equilibrium components commensurate with their relative concentration; and (c) species whose interconversion is intermediate on the NMR timescale. In the case of (c), one may observe a ‘coalescence’ of NMR signals which collapse into a single broad signal as the temperature is raised. The existence of such a ‘coalescence’ is necessary evidence that a dynamic chemical exchange process is actually occurring [species whose chemical shifts are similar undergo changes in T_2 (line broadening) as a function of temperature, producing spectra that give the false appearance of chemical exchange]. Furthermore, the analysis of such an exchange is best accomplished when the chemical shifts of the individual species are cleanly separated. Attempts to separate peaks that overlap severely can only result in significant errors (see *Chemical Exchange Effects on Spectra; Relaxation Effects of Chemical Exchange*).

4.2 Examples of Chemical Exchange

The most obvious examples of chemical exchange to be studied involve room temperature chloroaluminate melts and

^{27}Al NMR. The primary species expected to undergo exchange are included in the equilibrium

The ^{27}Al chemical shifts of the tetrachloro- and heptachloroaluminate anions given above are similar, creating a large error in any attempted mathematical analysis based on lineshapes alone. Unfortunately, studies of the chemical exchange (^{27}Al) of molten salts, where the authors have attempted to analyze equation (10), either deal with an impurity in the form of an oxide or else fail to provide examples of ‘clean’ reversible coalescence, as suggested earlier. The questionable use of preacquisition delay⁵ is also present in a number of the aforementioned analyses. A comprehensive review⁵ of ^{27}Al NMR is highly recommended, as it points out some of the many discrepancies in the few ^{27}Al chemical exchange papers in the literature.

5 DIFFUSION COEFFICIENTS

5.1 Introduction

The latest NMR method for determining self-diffusion coefficients involves the use of pulsed field gradients, as first demonstration by Stejskal and Tanner.²⁴ The recent availability of field gradient coils for all high-field NMR spectrometers guarantees that this technique²⁴ will replace various other methods (gravimetric, electrical, optical, radioactive, and stable tracers) that have been used to obtain diffusion data in molten salts (see *Diffusion Measurements by Magnetic Field Gradient Methods*).

5.2 Experimental Description

The pulsed field gradient experiment²⁴ is based on the use of two identical magnetic field pulses of duration t_1 and strength g inserted into the basic $90^\circ - \tau - 180^\circ$ spin echo sequence (see *Diffusion Measurements by Magnetic Field Gradient Methods and Field Gradients and Their Application*). The first gradient pulse is applied between the 90° and 180° rf pulses, effectively ‘labeling’ the position of individual nuclei in the sample. The second field gradient pulse is applied between the 180° pulse and the echo after a time t_2 . This second field gradient pulse monitors the movement (observation of the diffusion process) of any nuclear spins during t_2 . The effect of diffusion on the spin echo appearing at time 2τ is to decrease the echo amplitude relative to that observed in absence of gradient pulses. The echo attenuation is a quantitative measure for the precession frequency changes of diffusing nuclei during t_2 and allows the evaluation of the self-diffusion coefficient for the observed nucleus. The spin echo amplitude $M(2\tau, g)$ is given by

$$M(2\tau, g) = M(2\tau, 0) \exp\{-\gamma^2 D g^2 t_1^2 [t_2 - (t_1/3)]\} \quad (11)$$

5.3 Diffusion Coefficients

The spin echo method using pulsed field gradients was first used²⁵ successfully to determine a value of $2.30 \times 10^{-9} \text{ m}^2 \text{ s}^{-1}$

for the self-diffusion coefficient D of Na^+ in molten NaNO_3 , which is in excellent agreement with values obtained using other methods.

1 INTRODUCTION

Nuclear spins may exhibit several coherent phenomena occurring at nuclear magnetic resonance frequencies, which have their direct counterparts in resonant atomic systems.¹ For instance, nuclear free induction is an analog of atomic free induction and the spin echo is an analog of the photon echo. These analogies are due to the fact that an ensemble of identical spins forms a collective of finite-level objects, similar to a resonant system of atoms or molecules. Such a finite-level nonequilibrium system can, under special conditions, behave as a collection of coherent radiators.

Similar to the case of resonant atoms, one may distinguish two principally different ways of dealing with spin assemblies. One situation would be when spins are near their equilibrium state, with a nonequilibrium perturbation produced by a resonant alternating field. This is a situation typical of nuclear magnetic resonance.² Another possibility could be if spins are initially prepared in a strongly nonequilibrium state, e.g., being polarized against a constant external magnetic field. In the latter case, the polarized spins resemble a system of inverted resonant atoms.

One of the most interesting effects exhibited by a system of inverted atoms is superradiance, when the radiation intensity is approximately proportional to the number of atoms squared, while the duration of a superradiant pulse is inversely proportional to this number. The possibility of *atomic superradiance* was predicted by Dicke,³ and nowadays it is well studied both theoretically and experimentally. There exists a vast literature on the subject; a description can be found in recent books.^{4,5}

A natural question that arises is: if atomic and spin systems are so similar, then could a kind of *spin superradiance* be realized?

For spins to behave coherently, there must exist a cause correlating their motion. In the case of atoms, such a correlating mechanism is caused by the photon exchange through the common radiation field. This exchange results in the formation of effective interatomic correlations collectivizing atomic radiation. For spins, however, their magneto-dipole radiation is too weak to develop noticeable spin correlations. This concerns both nuclear as well as electron spins. Such photon-exchange interactions are negligible as compared to disordering dipolar spin interactions. How then might the spin motion be collectivized?

It is, of course, possible to force an ensemble of spins to develop coherence by imposing an initial condition of longitudinal magnetization, and using an rf pulse to produce a macroscopic transverse magnetization. But this would result in standard free nuclear induction, with the coherence being lost during the dephasing time T_2 . However, free nuclear induction, although it is a coherent process, is not superradiance with one of the main characteristic features of a short radiation time of a superradiant pulse $\tau_p \ll T_2$, shorter than the transverse dephasing time. To make the superradiant pulse time τ_p so short, some internal nonlinear correlating mechanism has to be involved.

Mutual spin correlations can arise owing to a feedback field formed by a resonant electric circuit coupled to the spin system and tuned to the Zeeman transition frequency of spins. The role of such a coupling in magnetic resonance experiments has been analyzed by Bloembergen and Pound.⁶ They showed that, in the presence of an electric resonant circuit, coupled to a spin system, the signal of nuclear induction can be damped in a time much smaller than T_2 . Since this shortening of the induction damping time is due to collective effects, caused by the spin coupling through the resonator feedback field, the resulting process may be termed *collective induction*. This effect has been observed in a number of substances.⁷ The process already possesses one of the prerequisites of superradiance, i.e., a short radiation time $\tau_p < T_2$. Usually, the induction signal starts at $t = 0$, at maximum intensity, while a superradiant pulse is always separated from the time origin by a delay time $t_0 > 0$. The signal of collective induction can also be peaked at a delay time well separated from $t = 0$. However, there is a principal difference between collective induction and superradiance: in collective induction, coherence is induced by external sources, while in superradiance coherence develops in a self-organized way due to internal correlations. The *self-organized, spontaneous*, nature of superradiance is one of its most important features.^{3–5} In general, one includes into the class of superradiant, the processes that are triggered by initial external pulses, but with a compulsory requirement that the imposed initial coherence be very weak, playing just the role of a trigger. Thus, collective induction, although it is a collective coherent process, is not yet superradiance.

The principal characteristics of superradiance, which apply both to atomic as well as to spin systems, can be summarized as follows:

1. Superradiance is collective, coherent radiation by an ensemble of radiators.
2. It is a spontaneous process developing in a self-organized way.

3. The maximal intensity of a superradiant burst is proportional to the number of radiators in the power larger than one.
4. The duration of a superradiant pulse is essentially shorter than the dephasing time T_2 .
5. A superradiant pulse has a peak at a finite delay time.

In atomic systems, one may distinguish different types of superradiance, all having the same characteristic features, including a short pulse time $\tau_p < T_2$ and finite delay time $t_0 > 0$. First, superradiance can occur as a transient process or as a lasting repeated effect, depending on whether there is no external nonresonant pumping permanently applied to the system or, respectively, there exists such a pumping supporting atomic inversion. In the first case, the system is prepared in an inverted state, after which no nonresonant pumping is involved. Then, if the relaxation process is gently promoted at $t = 0$ by an external pulse imposing weak initial coherence on the system, *triggered superradiance* may develop. When no initial coherence is thrust on the system, but superradiance appears as a completely self-organized effect starting from a purely incoherent state, then this is named *pure superradiance*. When the system is subject to the action of a nonresonant pumping constantly supporting atomic inversion, the regime of *pulsing superradiance* may arise, with a long series of superradiant bursts.

It has been of great interest to find out if a kind of spin superradiance, occurring in spin systems similarly to this phenomenon in atomic assemblies, could be realized experimentally and, if so, how should it be described theoretically. Despite several similarities between spin and atomic ensembles, they are, nevertheless, rather different. For example, spontaneous radiation, starting the process of pure atomic superradiance, is absent in spin assemblies. Therefore, one of the most intriguing questions has been if pure spin superradiance can exist and, if so, what would be its origin.

The phenomenon of spin superradiance is itself interesting and, in addition, it could be employed for several applications, as is discussed in Section 11. These applications could include:

1. *Investigation of materials characteristics* by measuring the relaxation parameters that are specific for spin superradiance and do not arise in other types of spin relaxation.
2. *Fast repolarization of targets* used in various scattering experiments of high-energy physics.
3. *Construction of spin masers* producing coherent radiation at radiofrequencies.
4. *Creation of sensitive detectors* of weak external pulses, based on the mechanism of triggered spin superradiance.
5. *Method of information processing*, derived from the feasibility of regulating the number of and the intervals between superradiant bursts in the regime of punctuated spin superradiance.

2 EXPERIMENTAL OBSERVATION

Historically, the regime of *pulsing spin superradiance* was observed first.^{8–10} This was done for a ruby crystal Al_2O_3 , with the Cr^{3+} paramagnetic admixture. The active nuclei were ^{27}Al , with spins $I = 5/2$. If the ruby crystal is oriented in an external magnetic field such that a fully resolved quadrupole structure of its five $\Delta m = \pm 1$ NMR

transitions can be observed, and a resonant circuit is tuned to a selected NMR line, then ^{27}Al spins form a fictitious two-level system. In experiments, the resonant circuit was tuned to the central $\{-1/2, 1/2\}$ line. The density of ^{27}Al nuclei was $\rho_{\text{Al}} = 4.4 \times 10^{22} \text{ cm}^{-3}$ and that of Cr^{3+} , $\rho_{\text{Cr}} = 8.6 \times 10^{18} \text{ cm}^{-3}$. The measurements were performed in a static magnetic field of about $B_0 = 1.1 \text{ T}$, which for the ^{27}Al magnetogyric ratio $7 \times 10^7 \text{ s}^{-1} \text{ T}^{-1}$ makes the NMR frequency $8 \times 10^7 \text{ Hz}$. The temperature range was from 1.6 to 4.2 K. The ringing time of the resonant circuit was $\tau = 10^{-6} \text{ s}$, and the quality factor Q was varied between 60 and 200. The coil filling factor was $\eta = 0.55$. The transverse spin damping time was $T_2 = 3 \times 10^{-5} \text{ s}$. The spin population inversion of the ^{27}Al nuclear spins was achieved by dynamic nuclear polarization, by means of powerful microwave radiation supplied to the sample in the vicinity of a selected Cr^{3+} electron spin resonance line. The corresponding longitudinal spin pumping time was $T_1^* = 0.1 \text{ s}$. The emission of a long train of superradiant bursts was observed, with the delay time of the first pulse being $t_0 = 2 \times 10^{-3} \text{ s}$ and its duration being $\tau_p = 2.6 \times 10^{-5} \text{ s}$ in the case of the quality factor $Q = 60$, while $\tau_p = 8 \times 10^{-6} \text{ s}$ for $Q = 200$.

The first observation of *pure spin superradiance* was accomplished in Dubna.^{11,12} A dielectric propanediol $\text{C}_3\text{H}_8\text{O}_2$, with a paramagnetic admixture of Cr^{5+} , was used as an active substance. This material possesses a high concentration of protons, with density $\rho_H = 4 \times 10^{22} \text{ cm}^{-3}$. The proton spins $I = 1/2$ played the role of radiators. The admixture of Cr^{5+} , with the density $\rho_{\text{Cr}} = 1.8 \times 10^{20} \text{ cm}^{-3}$, was employed for the purpose of dynamic nuclear polarization of proton spins. Experiments with the same material propanediol were repeated in Saint Petersburg.¹³ In all these experiments,^{11–13} electric circuits were used as resonators, with quality factors Q between 100 and 600. The filling factor was $\eta = 0.6$. The volume of samples varied from 0.5 cm^3 to 12 cm^3 . For external static magnetic fields B_0 in the interval between 0.5 T and 2.64 T, with the proton magnetogyric ratio $2.675 \times 10^8 \text{ s}^{-1} \text{ T}^{-1}$, the NMR proton frequencies were between $1.3 \times 10^8 \text{ Hz}$ and $7.1 \times 10^8 \text{ Hz}$. The experiments were carried out at low temperatures of 0.05–0.1 K. The inverted proton polarization reached 90%. Cooling of the sample resulted in strong suppression of the nuclear spin-lattice relaxation. The related longitudinal relaxation time was $T_1 = 1.8 \times 10^5 \text{ s}$ at $B_0 = 0.5 \text{ T}$ and $T_1 = 1.8 \times 10^6 \text{ s}$ at $B_0 = 2.64 \text{ T}$. The transverse dephasing time was $T_2 = 0.85 \times 10^{-5} \text{ s}$. After preparing an inverted sample, with the proton polarization directed against an external static magnetic field B_0 , the latter was scanned with the velocity about $5 \times 10^{-3} \text{ T s}^{-1}$. When in the process of this slow adiabatic scanning, the field value B_0 reached the value for which the proton NMR frequency coincided with the circuit natural frequency, the resonance condition was met. Then a powerful superradiant burst was produced, with the duration time about $\tau_p = 1.3 \times 10^{-6} \text{ s}$.

Similar experiments, observing pure spin superradiance, were accomplished in Bonn,¹⁴ with the target materials butanol ($\text{C}_4\text{H}_9\text{OH}$) and ammonia (NH_3). These materials are also rich with protons, with density $\rho_H \approx 3 \times 10^{23} \text{ cm}^{-3}$. By means of dynamic nuclear polarization, proton polarizations of up to 99% were achieved. The samples were cooled to low temperatures, the spin-lattice relaxation time was $T_1 \approx 3.6 \times 10^4 \text{ s}$ for protons in butanol and $T_1 \approx 10^5 \text{ s}$ for protons in ammonia.

Figure 1 Typical experimental setup for detecting spin superradiance. Of the two coils below, the left one plays the role of antenna, and the right one is part of the resonant electric circuit. The sample studied is shown as a dark bar inside the resonant coil. The upper left block is an oscilloscope, and the lower one is a plotter

The resonant electric circuit, with the quality factor $Q = 33$, had a resonance frequency of 1.6×10^8 Hz.

In different experiments, slightly different setups were employed. A typical arrangement^{11,12} is shown in Figure 1. The characteristic superradiant pulse^{11,12} is presented in Figure 2.

Figure 2 Voltage signal corresponding to a superradiant pulse as a function of time, measured in units of 10^{-7} s, for two initial spin polarizations, $s_0 = 0.52$ (lower curve) and $s_0 = 0.57$ (upper curve)

A series of numerical simulations were accomplished,^{15,16} which could be considered as computer experiments modeling the behavior of spins in conditions typical of experimental observations. These computer simulations confirmed the existence of both pure as well as triggered spin superradiance, and are in good agreement with experiments.

3 BASIC MODEL

Since the phenomenon of spin superradiance exists in nature, it is necessary to develop its theoretical description. The simplest idea would be to invoke the Bloch equations for this purpose. However, these are designed so that they treat the magnetization of a sample as a macroscopic vector, which presupposes the existing coherence from the very beginning. If at the initial time, coherence of spins is absent, the Bloch equations would never display it. Therefore, these equations can describe only triggered spin superradiance, when coherence is thrust upon spins at the initial time by assuming the presence of nonzero transverse magnetization. But pure spin superradiance, being a self-organized coherent process, cannot in principle be treated by the Bloch equations. A discussion of this problem as well as the related references can be found in a review.¹⁷ In order to be able to describe all possible regimes of spin dynamics, it is necessary to resort to microscopic models. A theory of *nuclear spin superradiance*, based on realistic Hamiltonians typical of nuclear spin assemblies in condensed matter^{1,2,18} has been previously developed.¹⁹⁻²⁴

A system of N nuclear spins, enumerated by an index $i = 1, 2, \dots, N$, is characterized by their spin operators $\hat{\mathbf{I}}_i$. The Hamiltonian of nuclear spins in a solid can be written as a sum

$$\hat{H}_{\text{nuc}} = \sum_i \hat{H}_i + \frac{1}{2} \sum_{i \neq j} \hat{H}_{ij} \quad (1)$$

of the Zeeman term and of a part due to many-body spin interactions. The Zeeman term contains

$$\hat{H}_i = -\hbar \gamma_n \mathbf{B} \cdot \hat{\mathbf{I}}_i \quad (2)$$

where $\mathbf{B}$ is the total magnetic field and γ_n is the nuclear magnetogyric ratio. The total magnetic field

$$\mathbf{B} = B_0 \mathbf{e}_z + (B_1 + H) \mathbf{e}_x \quad (3)$$

consists of a static magnetic field B_0 along the z -axis and of a transverse field being a sum of an external field B_1 and of a field H produced by an electric coil into which the sample is immersed. The corresponding orientation of the coordinate axes with respect to the sample is explained in Figure 3. The static magnetic field is directed so that

$$\gamma_n B_0 < 0 \quad (4)$$

In general, the nuclear magnetogyric ratio can be positive as well as negative. If it is positive, then inequality (4) states that the static field is negative. In this case, the initial polarization

Figure 3 Orientation of the coordinate axes with respect to the sample that is inserted into the coil of a resonant electric circuit

of the sample nuclei is called inverted if it is positive, i.e., directed against the static magnetic field.

The basic force acting between nuclear spins is due to the dipolar interactions which may be described by the Hamiltonian

$$\hat{H}_{ij} = \sum_{\alpha\beta} D_{ij}^{\alpha\beta} \hat{I}_i^\alpha \hat{I}_j^\beta \quad (5)$$

where the upper indices α and β denote the coordinate components $\alpha, \beta = x, y, z$, while

$$D_{ij}^{\alpha\beta} = \frac{\hbar^2 \gamma_n^2}{r_{ij}^3} (\delta_{\alpha\beta} - 3n_{ij}^\alpha n_{ij}^\beta) \quad (6)$$

is the dipolar tensor, in which

$$r_{ij} \equiv |\mathbf{r}_{ij}|, \quad n_{ij} \equiv \frac{\mathbf{r}_{ij}}{r_{ij}}, \quad \mathbf{r}_{ij} \equiv \mathbf{r}_i - \mathbf{r}_j$$

The dipolar tensor satisfies the equalities

$$\sum_{\alpha} D_{ij}^{\alpha\alpha} = 0, \quad \sum_{j(\neq i)} D_{ij}^{\alpha\beta} = 0 \quad (7)$$

of which the first is exact and the second is asymptotically valid for a macroscopic sample.

For practical purpose, it is convenient to work with the ladder spin operators $\hat{I}_j^\pm \equiv \hat{I}_j^x \pm i\hat{I}_j^y$, called the raising and lowering spin operators, respectively. Then, with the help of the notation

$$\begin{aligned} a_{ij} &\equiv D_{ij}^{zz}, & b_{ij} &\equiv \frac{1}{4}(D_{ij}^{xx} - 2iD_{ij}^{xy} - D_{ij}^{yy}) \\ c_{ij} &\equiv \frac{1}{2}(D_{ij}^{xz} - iD_{ij}^{yz}) \end{aligned} \quad (8)$$

the Zeeman term (2), for the total field (3), becomes

$$\hat{H}_i = -\hbar\gamma_n B_0 \hat{I}_i^z - \frac{1}{2}\hbar\gamma_n (B_1 + H)(\hat{I}_i^+ + \hat{I}_i^-) \quad (9)$$

and the dipolar interaction (5) takes the form

$$\begin{aligned} \hat{H}_{ij} &= a_{ij} \left(\hat{I}_i^z \hat{I}_j^z - \frac{1}{2} \hat{I}_i^+ \hat{I}_j^- \right) + b_{ij} \hat{I}_i^+ \hat{I}_j^+ + b_{ij}^* \hat{I}_i^- \hat{I}_j^- \\ &\quad + 2c_{ij} \hat{I}_i^+ \hat{I}_j^z + 2c_{ij}^* \hat{I}_i^- \hat{I}_j^z \end{aligned} \quad (10)$$

Equations (9) and (10) will be used below to derive the evolution equations.

The electric circuit, coupled with the spin sample, is characterized by resistance R , inductance L , and capacity C . The coil, surrounding the sample, has n turns of cross-section area A_c over a length l . The electric current j of the circuit is given by the Kirchhoff equation

$$L \frac{dj}{dt} + Rj + \frac{1}{C} \int_0^t j(t') dt' = \tilde{E} - \frac{d\Phi}{dt} \quad (11)$$

in which $\tilde{E}$ is an electromotive force, if any, and Φ is a magnetic flux

$$\Phi = \frac{4\pi}{c} n A_c \eta M_x \quad (12)$$

formed by the x -component of the magnetization density

$$M_x = \frac{\hbar\gamma_n}{V} \sum_i \langle \hat{I}_i^x \rangle \quad (13)$$

Here the brackets $\langle \dots \rangle$ imply statistical averaging. The filling factor η is approximately equal to $\eta \approx V/V_c$, where V is the sample volume, while $V_c \equiv A_c l$ is the coil volume.

The electric current in the circuit is formed by moving transverse spins. In its turn, the current, circulating over the coil, produces a feedback magnetic field

$$H = 4\pi \frac{nj}{cl} \quad (14)$$

Hence, the Kirchhoff equation (11) can be rewritten for the feedback field (14). To this end, it is useful to employ the notation for the natural circuit frequency

$$\omega \equiv \frac{1}{\sqrt{LC}} \quad \left(L \equiv 4\pi \frac{n^2 A_c}{c^2 l} \right) \quad (15)$$

and for the circuit ringing time

$$\tau \equiv \frac{1}{\gamma} \quad \left(\gamma \equiv \frac{R}{2L} \right) \quad (16)$$

The related circuit damping

$$\gamma = \frac{\omega}{2Q} \quad \left(Q \equiv \frac{\omega L}{R} \right) \quad (17)$$

is connected with the quality factor Q . Employing this notation, together with that for the reduced electromotive force

$$h \equiv \frac{c\tilde{E}}{nA_c\gamma} \quad (18)$$

from the Kirchhoff equation (11), one obtains the result

$$\frac{dH}{dt} + 2\gamma H + \omega^2 \int_0^t H(t')dt' = \gamma h - 4\pi\eta \frac{dM_x}{dt} \quad (19)$$

for the feedback magnetic field (14).

The feedback equation (19) can be presented in a form that is extremely useful to exploit for analysing the evolution equations.²⁰ By involving the method of Laplace transforms and introducing the transfer function

$$G(t) = \left(\cos \tilde{\omega}t - \frac{\gamma}{\tilde{\omega}} \sin \tilde{\omega}t \right) e^{-\gamma t}$$

with $\tilde{\omega} \equiv \sqrt{\omega^2 - \gamma^2}$, equation (19) can be presented as the integral

$$H = \int_0^t G(t-t') [\gamma h(t') - 4\pi\eta \dot{M}_x(t')] dt' \quad (20)$$

where the dot over $\dot{M}_x$ means, as usual, time derivative.

4 EVOLUTION EQUATIONS

The equations of motion for the nuclear spin operators are given by the corresponding Heisenberg equations. From these we can derive the equations for the following statistical averages. The function

$$u \equiv \frac{1}{I} \langle \hat{I}_i^- \rangle \quad (21)$$

defines the rotation of transverse spin components. The degree of coherence in this rotation is described by

$$w \equiv \frac{1}{I^2} \langle \hat{I}_i^+ \rangle \langle \hat{I}_i^- \rangle = |u|^2 \quad (22)$$

The average

$$s \equiv \frac{1}{I} \langle \hat{I}_i^z \rangle \quad (23)$$

gives the longitudinal spin polarization, which is analogous to the population difference in optic systems. Keeping in mind that wavelengths at radio frequencies are much larger than mean distances between spins and usually even essentially larger than linear sizes of a sample, one may employ the uniform approximation, assuming that the functions (21)–(23) do not depend on spatial variables.

In order to obtain the evolution equations for the quantities (21)–(23), the Heisenberg equations are averaged for the corresponding spin operators. In doing so, one encounters the known problem of the resulting equations being not closed but containing, in addition to u , w , and s , binary averages of spin operators. The standard way of closing these equations would be to employ mean-field decoupling, when the binary

average $\langle \hat{I}_i^\alpha \hat{I}_j^\beta \rangle$, with $i \neq j$, is factorized onto the product $\langle \hat{I}_i^\alpha \rangle \langle \hat{I}_j^\beta \rangle$. Such a decoupling, however, ends with Bloch-type equations having the same deficiency of never exhibiting coherence if at the initial time $w(0) = 0$. This is because the mean-field decoupling completely neglects spin correlations leading to local spin fluctuations. Taking account of such fluctuations is a necessary prerequisite for describing pure spin superradiance.

Another possibility for closing the hierarchy of spin evolution equations could be by writing additional equations for the binary correlators $\langle \hat{I}_i^\alpha \hat{I}_j^\beta \rangle$ and by decoupling only the higher-order correlators, retaining the binary ones untouched. Unfortunately, this drastically increases the number of equations and so complicates the problem that it becomes practically untreatable even for equilibrium magnets;²⁵ the more so for nonequilibrium systems presented by nonlinear differential equations.

To render the set of spin evolution equations closed in order to keep the problem treatable and, at the same time, to take into account local spin fluctuations, one can apply the *method of stochastic decoupling*.^{19–21,24} The main idea of the latter is to separate in the evolution equations the terms describing long-range correlations from the terms related to short-range fluctuations. Employing the method of restricted traces, one may define two types of statistical averages, one incorporating only long-range correlations and another involving short-range fields that are treated as stochastic variables. In what follows, the first type of averaging is denoted by the single angle brackets $\langle \dots \rangle$, while the second type, by the double brackets $\langle\langle \dots \rangle\rangle$. Then, the binary spin correlators are presented as

$$\langle \hat{I}_i^\alpha \hat{I}_j^\beta \rangle = \langle \hat{I}_i^\alpha \rangle \langle \hat{I}_j^\beta \rangle \quad (i \neq j) \quad (24)$$

where the averaging does not touch stochastic variables which enter the evolution equations in the following linear combinations:

$$\begin{aligned} \xi_0 &\equiv \frac{1}{\hbar} \sum_{j(\neq i)} (a_{ij} \hat{I}_j^z + c_{ij} \hat{I}_j^+ + c_{ij}^* \hat{I}_j^-) \\ \xi &\equiv -\frac{i}{\hbar} \sum_{j(\neq i)} \left(\frac{1}{2} a_{ij} \hat{I}_j^- - 2b_{ij} \hat{I}_j^+ - 2c_{ij} \hat{I}_j^z \right) \end{aligned} \quad (25)$$

with the coefficients defined in equation (8). Stochastic variables (25) describe local fluctuating fields which act on neighbor spins forcing them to move. The existence of such fluctuating fields should lead to the appearance of dipolar dynamic broadening.²⁶ To completely define the problem, it is necessary to prescribe the rules for calculating stochastic averages over the random variables (25). This can be done by considering the stochastic variables (25) as a white-noise process characterized by the stochastic averages

$$\begin{aligned} \langle\langle \xi_0(t) \rangle\rangle &= \langle\langle \xi(t) \rangle\rangle = 0, \quad \langle\langle \xi_0(t) \xi_0(t') \rangle\rangle = 2\Gamma_3 \delta(t-t') \\ \langle\langle \xi_0(t) \xi(t') \rangle\rangle &= \langle\langle \xi(t) \xi(t') \rangle\rangle = 0, \quad \langle\langle \xi^*(t) \xi(t') \rangle\rangle = 2\Gamma_3 \delta(t-t') \end{aligned} \quad (26)$$

where Γ_3 is the width of *dynamic broadening* due to local dipole interactions of nuclei. This is a sort of inhomogeneous broadening existing in addition to the homogeneous broadening yielding the longitudinal, $\Gamma_1 \equiv T_1^{-1}$, and transverse, $\Gamma_2 \equiv T_2^{-1}$, relaxation widths.

6 PHYSICAL APPLICATIONS

To obtain the resulting evolution equations in a compact form, it is convenient to introduce the notation

$$f \equiv -i\gamma_n(B_1 + H) + \xi \quad (27)$$

for an effective force acting on a spin. The transverse external magnetic field B_1 may, in general, contain a static as well as an alternating term, as

$$B_1 = h_1 + h_2 \cos \omega t \quad (28)$$

where, for simplicity, the frequency of the alternating field is assumed to be in resonance with the frequency of the electric circuit. Recall that the magnetic field H , produced by the coil, is caused by a feedback field and, possibly, by a field of an electromotive force, which may be presented as

$$h(t) = h_0 \cos \omega t \quad (29)$$

Finally, the NMR frequency is denoted by

$$\omega_0 \equiv |\gamma_n B_0| \quad (30)$$

Then the evolution equations for the functions (21) to (23) acquire the form

$$\frac{du}{dt} = -i(\omega_0 + \xi_0 - i\Gamma_2)u + fs \quad (31)$$

$$\frac{dw}{dt} = -2\Gamma_2 w + (u^* f + f^* u)s \quad (32)$$

$$\frac{ds}{dt} = -\frac{1}{2}(u^* f + f^* u) - \Gamma_1(s - \zeta) \quad (33)$$

where ζ is an average stationary value for a z -component of a spin. Generally, $-1 \leq \zeta \leq 1$. When there is no external pumping, then $\zeta = -1$. In the presence of pumping, e.g., by means of dynamic nuclear polarization, the pumping parameter $\zeta > -1$ and can reach the value $\zeta = 1$. Equations (31)–(33) compose a nonlinear system of stochastic differential equations describing all dynamic properties of nuclear spins.

The system of evolution equations (31)–(33) still looks rather complicated. Fortunately, there are several small parameters that allow one to simplify the situation by employing the *scale separation approach*^{19–21,27} which is a generalization of the Krylov–Bogolubov averaging technique²⁸ to stochastic and partial differential equations. The existing small parameters are connected with the relatively small values of the relaxation widths Γ_1 and Γ_2 as compared to the NMR frequency (30), so that

$$\frac{\Gamma_1}{\omega_0} \ll 1, \quad \frac{\Gamma_2}{\omega_0} \ll 1 \quad (34)$$

Clearly, the quantity

$$\Gamma_0 \equiv \pi \eta \rho_n \gamma_n^2 \hbar I \quad \left(\rho_n \equiv \frac{N}{V} \right) \quad (35)$$

is also small with respect to ω_0 , as well as the dynamic broadening width Γ_3 , that is

$$\frac{\Gamma_0}{\omega_0} \ll 1, \quad \frac{\Gamma_3}{\omega_0} \ll 1 \quad (36)$$

All amplitudes of the applied transverse fields are also assumed to be small, which implies that the values

$$v_0 \equiv \gamma_n h_0, \quad v_1 \equiv \gamma_n h_1, \quad v_2 \equiv \gamma_n h_2 \quad (37)$$

satisfy the inequalities

$$\frac{|v_0|}{\omega_0} \ll 1, \quad \frac{|v_1|}{\omega_0} \ll 1, \quad \frac{|v_2|}{\omega_0} \ll 1 \quad (38)$$

The electric circuit, coupled to the spin system, is supposed to be of good quality, having a high quality factor, which means that the ringing width is small compared to the natural circuit frequency,

$$\frac{\gamma}{\omega} \ll 1 \quad (Q \gg 1) \quad (39)$$

The last parameter, though not the least, is that the electric circuit has to be tuned to the NMR frequency (30), hence the resonance condition for the detuning Δ must be valid:

$$\frac{|\Delta|}{\omega_0} \ll 1 \quad (\Delta \equiv \omega - \omega_0) \quad (40)$$

In this way, the circuit plays the role of a resonator.

The existence of the small parameters makes it possible, by analyzing the right-hand sides of the evolution equations (31)–(33), to conclude that the function u has to be classified as fast, as compared to the slow functions w and s . Conversely, the functions w and s are quasi-invariants with respect to u . In addition, one may derive an explicit expression for the resonator magnetic field H by iterating its integral representation with the solution of equation (31), where only the main term in the right-hand side is retained. This iteration gives

$$\gamma_n H = i\alpha(u - u^*) + \beta \cos \omega t \quad (41)$$

where the first term, with the coupling function

$$\alpha \equiv \frac{\Gamma_0 \omega_0}{\gamma} (1 - e^{-\gamma t}) \quad (42)$$

is caused by the feedback coupling of spins with the resonator, and the second term, with the coupling

$$\beta \equiv \frac{v_0}{2} (1 - e^{-\gamma t}) \quad (43)$$

is due to an electromotive force. The time dependence of the coupling functions (42) and (43) describes the retardation in the resonator action on spins. Expressions (42) and (43) are written here for the case of small detuning, such that $|\Delta| \ll \gamma$. The latter assumption is not critical but is employed solely for the simplification of formulas. Relation (41) holds true for any detuning satisfying the resonance condition (40).

Substituting relation (41) in equations (31)–(33) and using the notation

$$f_1 \equiv -iv_1 - i(v_2 + \beta) \cos \omega t + \xi \quad (44)$$

one comes to the evolution equations

$$\frac{du}{dt} = -[i(\omega_0 + \xi_0) + \Gamma_2 - \alpha s]u + f_1 s - \alpha s u^* \quad (45)$$

$$\frac{dw}{dt} = -2(\Gamma_2 - \alpha s)w + (u^* f_1 + f_1^* u)s - \alpha s[(u^*)^2 + u^2] \quad (46)$$

$$\frac{ds}{dt} = -\alpha w - \frac{1}{2}(u^* f_1 + f_1^* u) - \Gamma_1(s - \zeta) + \frac{1}{2}\alpha[(u^*)^2 + u^2] \quad (47)$$

Following the scale separation approach further, equation (45) for the fast function u can be solved, with w and s being quasi-invariants. The solution obtained is substituted in the right-hand sides of equations (46) and (47), which are averaged over the period $2\pi/\omega_0$ of fast oscillations as well as over stochastic variables defined in equation (25). Then, introducing the effective attenuation width

$$\Gamma_{\text{eff}} \equiv \Gamma_3 - \alpha \frac{v_1^2}{\omega_0^2} s - \frac{v_1(v_2 + \beta)\Gamma}{2\omega_0^2} e^{-\Gamma t} + \frac{(v_2 + \beta)^2}{4\Gamma} (1 - e^{-\Gamma t}) \quad (48)$$

where

$$\Gamma \equiv \Gamma_2 - \alpha s + \Gamma_3$$

reduces equations (46) and (47) for slow functions to the evolution equations

$$\frac{dw}{dt} = -2(\Gamma_2 - \alpha s)w + 2\Gamma_{\text{eff}} s^2 \quad (49)$$

$$\frac{ds}{dt} = -\alpha w - \Gamma_{\text{eff}} s - \Gamma_1(s - \zeta) \quad (50)$$

In the form of the widths (48), it is again assumed that the detuning is small, such that $|\Delta| \ll |\gamma| \ll \omega_0$, which is not critical but just simplifies cumbersome expressions.

The evolution equations (49) and (50) are the main equations describing the dynamics of strongly nonequilibrium nuclear spins. The analysis of these equations makes it possible to study various regimes of spin motion.

5 NYQUIST NOISE

The main problem is: What is the origin of pure spin superradiance? In other words, what initiates the motion of spins when no coherence is thrust upon the system at $t = 0$ and there are no external fields pushing spins in the transverse direction?

Keeping in mind the analogy with atomic assemblies, one may remember that in an inverted system of atoms the relaxation process begins with atomic spontaneous radiation, which is a quantum process. After the seed radiation field appears in the system, atomic correlations start arising through the interatomic photon exchange. As soon as these correlations become sufficiently intensive, coherence develops. Then, the quantum stage of spontaneous emission changes for the coherent stage, when atoms are correlated and emit coherently, which results in superradiance.

The collectivization of spins can be produced by means of the resonator feedback field. But for this field to arise, the spins first have to start their motion. Spontaneous emission for spins

is absent. Then, what could initiate the motion of spins? What mechanism would be the origin of pure spin superradiance?

There existed a widespread delusion that the thermal Nyquist noise of the resonant electric circuit could be the initiating cause of spin rotation. At this point, it is necessary to stress that the role of the thermal Nyquist noise in producing a fluctuating torque on the magnetization was discussed in detail by Bloembergen and Pound in their classic paper.⁶ They showed that the average thermal damping is inversely proportional to the sample volume; thus this damping is noticeable only for a single spin. For a macroscopic sample of many spins $N \gg 1$ the coil thermal damping should be negligibly small. This analysis seems to have been completely forgotten by later workers who have proclaimed the leading role of the coil thermal noise in initiating spin rotation.

To explicitly illustrate the role of the thermal Nyquist noise, one has to consider the effective attenuation width (48), including the influence of the electromotive force related to the resonance mode of the thermal noise.¹⁹⁻²¹ When there are no external transverse magnetic fields, that is when $v_1 = v_2 = 0$, the effective width (48) reads

$$\Gamma_{\text{eff}} = \Gamma_3 + \frac{v_0^2}{16\Gamma} (1 - e^{-\Gamma t}) (1 - e^{-\gamma t})^2 \quad (51)$$

The electromotive force, corresponding to the resonator thermal noise, can be written as

$$\tilde{E} = \tilde{E}_0 \cos \omega t \quad (52)$$

The related magnetic field, defined in equations (18) and (29), has the amplitude

$$h_0 = \frac{c\tilde{E}_0}{nA_c\gamma} \quad (53)$$

From here, it follows that

$$h_0^2 = 8\pi \frac{\eta \rho_n \tilde{E}_0^2}{\gamma R N} \quad (54)$$

With the definition (37), one gets the quantity

$$v_0^2 = \frac{8\Gamma_0 \tilde{E}_0^2}{\hbar \gamma I R N} \quad (55)$$

which characterizes in equation (51) the average thermal damping due to the Nyquist noise.

First, equation (51) shows that the thermal damping at $t = 0$ is exactly zero because of the temporal factors. The latter become essential only for $t > T_2, \tau$. Therefore, the influence of the thermal noise at short times should be suppressed by these temporal factors.

Moreover, the quantity (55) is inversely proportional to the number of spins. That is, the thermal damping is inversely proportional to N , and thus it should be negligibly small for a macroscopic sample with $N \gg 1$. This is in complete agreement with the conclusion of Bloembergen and Pound.⁶

To be more precise, it is possible to explicitly calculate the quantity (55) by substituting the square amplitude of the electromotive force due to the thermal noise,⁷ which is

$$\tilde{E}_0^2 = \frac{\hbar \omega}{2\pi} \gamma R \coth \frac{\hbar \omega}{2k_B T} \quad (56)$$

At radio frequencies, the inequality

$$\frac{\omega}{\omega_T} \ll 1 \quad \left(\omega_T \equiv \frac{k_B T}{\hbar} \right) \quad (57)$$

is valid. As a result, equation (56) simplifies to

$$\tilde{E}_0^2 \simeq \frac{\hbar}{\pi} \gamma R \omega_T \quad (58)$$

Thence, equation (55) becomes

$$v_0^2 = \frac{8\Gamma_0 \omega_T}{\pi I N} \quad (59)$$

Expression (51) shows that the thermal damping has to be compared to the dynamic broadening width Γ_3 , which can be of order of Γ_2 . When the inequality

$$\frac{v_0^2}{\Gamma_2^2} \ll 1 \quad (60)$$

holds true, the thermal damping can be safely neglected, playing no role in spin relaxation, as compared to the dynamic broadening.

To estimate the factor (59) and, respectively, to check the inequality (60), one can accept the values typical of experiments on proton spin superradiance.¹¹⁻¹³ Then, for the filling factor $\eta = 0.6$, proton density $\rho_n = 4 \times 10^{22} \text{ cm}^{-3}$, and the proton magnetogyric ratio $\gamma_n = 2.675 \times 10^8 \text{ s}^{-1} \text{ T}^{-1}$, the linewidth (35) is $\Gamma_0 = 2.846 \times 10^4 \text{ Hz}$. At temperature $T = 0.1 \text{ K}$, the thermal frequency is $\omega_T = 1.309 \times 10^{11} \text{ Hz}$. Under the static magnetic field $B_0 = 1 \text{ T}$, the proton NMR frequency is $\omega_0 = 2.675 \times 10^8 \text{ Hz}$. The ratio $\omega/\omega_T \sim 10^{-3}$ is small. With the transverse relaxation width $\Gamma_2 = 1.176 \times 10^5 \text{ Hz}$, one obtains

$$\frac{v_0^2}{\Gamma_2^2} = \frac{1.37}{N} \times 10^6$$

For a sample volume of about 1 cm^3 and $N \sim 10^{23}$, one has $v_0^2/\Gamma_2^2 \sim 10^{-17}$. This ratio is so small that, clearly, the thermal Nyquist noise is not able to play any role in spin relaxation in a macroscopic sample. It is only for the number of spins $N \leq 10^6$, when the thermal noise becomes noticeable. When considering macroscopic samples, with $N \gg 10^6$, the resonator thermal noise can be neglected.

6 INCOHERENT STAGE

At the initial stage, the main role in starting spin relaxation is played by the dynamic broadening due to local spin fluctuations. Omitting in the effective width, (48), the terms of second order with respect to small parameters and neglecting the resonator thermal noise by setting $\beta \rightarrow 0$, one has

$$\Gamma_{\text{eff}} = \Gamma_3 + \frac{v_0^2}{4\Gamma} (1 - e^{-\Gamma t}) \quad (61)$$

This equation shows that at the very beginning of the process, when $t \rightarrow 0$, then $\Gamma_{\text{eff}} \rightarrow \Gamma_3$. That is, the dynamic

broadening width Γ_3 makes the major contribution to the effective relaxation width, equation (61).

For asymptotically small times $t \rightarrow 0$, the coupling function (42) is close to zero, $\alpha \rightarrow 0$. Then the evolution equations (49) and (50) can be reduced to the form

$$\frac{dw}{dt} = -2\Gamma_2 w + 2\Gamma_3 s^2, \quad \frac{ds}{dt} = -\Gamma_1^* (s - \zeta^*) \quad (62)$$

in which

$$\Gamma_1^* \equiv \Gamma_1 + \Gamma_3, \quad \zeta^* \equiv \frac{\Gamma_1}{\Gamma_1^*} \zeta \quad (63)$$

The solutions to equations (62) are

$$w = w_0 e^{-2\Gamma_2 t} + 2\Gamma_3 \int_0^t s^2(t') e^{-2\Gamma_2(t-t')} dt',$$

$$s = \zeta^* + (s_0 - \zeta^*) e^{-\Gamma_1^* t} \quad (64)$$

which demonstrates the character of spin motion at short times $t \rightarrow 0$. At this stage, the motion of spins is still completely incoherent, since, because of retardation, the coupling with the resonator has not yet been switched on. Assuming that $\Gamma_1 \ll \Gamma_3$, hence $\zeta^* \ll 1$, one may simplify the solution (64) as

$$w \simeq w_0 e^{-2\Gamma_2 t} + \frac{\Gamma_3 s_0^2}{\Gamma_2 - \Gamma_3} (e^{-2\Gamma_3 t} - e^{-2\Gamma_2 t}), \quad s \simeq s_0 e^{-\Gamma_3 t}$$

The initial *incoherent stage* of spin relaxation can also be called the *quantum stage*, as long as the relaxation is caused by quantum effects of spin-spin interactions and there are yet no collective effects that could lead to the development of coherence.

The duration of the incoherent quantum stage lasts until the *quantum time* t_q , when the coupling function (42) reaches the value Γ_2 , so that

$$\alpha(t_q) = \Gamma_2 \quad (65)$$

and when taking account of collective effects, due to the coupling with the resonator, becomes important. It is also easy to notice that the difference $\Gamma_2 - \alpha s$ in equation (49) may change its sign at the quantum time t_q , which means that the generation of coherent radiation would begin. Combining equations (42) and (65) for the quantum time gives

$$t_q = \tau \ln \frac{g}{g-1} \quad (66)$$

where the notation of the effective coupling parameter

$$g \equiv \frac{\Gamma_0 \omega_0}{\Gamma_2 \gamma} = 2Q \frac{\Gamma_0}{\Gamma_2} \quad (67)$$

is introduced. The quantum time (66) is positive only for $g > 1$. If $g = 1$, then $t_q \rightarrow \infty$. This indicates that the quantum stage is finite and may change to a collective stage only if the coupling parameter (67) is $g > 1$. If the spin-resonator coupling is weak, and $g \leq 1$, only the quantum stage exists, and the collective stage never comes into being. For sufficiently strong coupling, equation (66) gives

$$t_q \simeq \frac{\tau}{g} \quad (g \gg 1) \quad (68)$$

The values of solutions (64) at the end of the quantum stage, i.e., at t_q , can be estimated assuming that $t_q \ll T_2$ and $t_q \ll T_3 \equiv \Gamma_3^{-1}$. Then equation (64) yields

$$w(t_q) \simeq w_0 + 2\delta_3 s^2, \quad s(t_q) \simeq s_0 \quad (69)$$

where

$$\delta_3 \equiv \frac{\Gamma_3}{g\gamma} = \frac{\Gamma_2 \Gamma_3}{\Gamma_0 \omega_0} \quad (70)$$

This is a small parameter, since $\Gamma_0 \sim \Gamma_3$ while $\Gamma_2 \ll \omega$. But, no matter how small δ_3 is, it can be important if $w_0 = 0$.

7 TRANSIENT SUPERRADIANCE

After the incoherent quantum stage, the coupling function (42) increases, switching on collective effects resulting in the appearance of spin superradiance.^{19–21} An accurate description of this process can be made by solving the evolution equations (49) and (50) numerically. It is also possible to present an explicit analytical description of how superradiance develops for the transient stage, when the time is larger than the quantum time t_q but yet much smaller than the spin-lattice relaxation time T_1 . Then, the term with Γ_1 in equation (50) can be omitted. If there are no strong external transverse fields, then one should set $v_1 \rightarrow 0$ and $v_2 \rightarrow 0$. Assuming that the coupling function (42) has reached its maximal value, one gets $\alpha \approx g\Gamma_2$. The dynamic broadening width Γ_3 is not larger than Γ_2 . Hence, for a sufficiently large coupling parameter g , one may neglect Γ_3 as compared to $g\Gamma_2 \gg \Gamma_3$. Under these conditions, equations (49) and (50) read

$$\frac{dw}{dt} = -2\Gamma_2(1 - gs)w, \quad \frac{ds}{dt} = -g\Gamma_2 w \quad (71)$$

Initial conditions for equation (71) should be taken at $t = t_q$.

Equations (71) can be solved exactly^{19–21} yielding

$$w = \left(\frac{\Gamma_p}{g\Gamma_2} \right)^2 \text{sech}^2 \left(\frac{t - t_0}{\tau_p} \right), \quad s = -\frac{\Gamma_p}{g\Gamma_2} \tanh \left(\frac{t - t_0}{\tau_p} \right) + \frac{1}{g} \quad (72)$$

Here Γ_p is a pulse width, $\tau_p = \Gamma_p^{-1}$ is a pulse time, and t_0 is a delay time. These parameters are the integration constants that are to be defined from initial conditions $w(t_q)$ and $s(t_q)$ taken at the boundary of the transient stage, that is at the quantum time t_q . Employing equations (69) results in

$$\Gamma_p^2 = \Gamma_g^2 + (g\Gamma_2)^2(w_0 + 2\delta_3 s_0^2), \quad \Gamma_g \equiv \Gamma_2(1 - gs_0), \quad \Gamma_p \tau_p = 1 \quad (73)$$

while the delay time is

$$t_0 = t_q + \frac{\tau_p}{2} \ln \left| \frac{\Gamma_p - \Gamma_g}{\Gamma_p + \Gamma_g} \right| \quad (74)$$

Solutions (72) demonstrate that the coherence intensity $w(t)$ has the shape of a burst of width τ_p and peaked at the delay time t_0 .

If the spin-resonator coupling g is sufficiently weak or the initial spin polarization s_0 is sufficiently small, so that $gs_0 \leq 1$, then the value of the delay time (74) shifts to the quantum region, becoming $t_0 \leq t_q$. This means that the radiation intensity would not have the shape of a coherent burst, but is rather a decreasing function of time, typical of nuclear induction. In the case of an external pulse thrusting an essential initial coherence onto the spins, such that $g^2 w_0 > 1$, the radiation time τ_p is small, $\tau_p < T_2$, which is characteristic of collective induction. When $gs_0 > 1$ and $g^2 w_0 > 1$, the signal of collective induction is peaked at a finite delay time $t_0 > 0$. As is explained in the introduction, collective induction, with coherence induced by an initial external source, is in principle different from superradiance that is a process of spontaneously arising coherence.

For solutions (72) to describe a superradiant burst, the requirements discussed in the introduction must be satisfied. In order that the initial coherence, given by w_0 , does not essentially influence the pulse width Γ_p ,

$$g^2 w_0 < 1 \quad (75)$$

This guarantees a basically spontaneous character of the process. Then, the pulse time τ_p is to be sufficiently short and the delay time finite,

$$\tau_p < T_2, \quad t_q < t_0 < \infty \quad (76)$$

The second of these inequalities yields

$$gs_0 > 1, \quad w_0 + 2\delta_3 s_0^2 > 0 \quad (77)$$

Combining all conditions (75)–(77), one sees that there exist two types of transient spin superradiance, whose classification, taking account of the smallness of the parameter $\delta_3 \ll 1$, can be accomplished as follows:

1. *Triggered superradiance*, when

$$gs_0 > 1 + \sqrt{1 - g^2 w_0}, \quad w_0 \neq 0$$

Here, a weak external pulse imposes an initial coherence on spins, but, being rather weak, this pulse plays just the role of a trigger, while the following development of coherence is mainly governed by internal properties.

2. *Pure superradiance*, when

$$gs_0 > 2, \quad w_0 = 0$$

This is a purely self-organized process, with no coherence prescribed from external sources.

In the case of pure spin superradiance, the characteristic quantities (73) and (74), having regard to $\delta_3 \ll 1$, become

$$\begin{aligned}\Gamma_p &\simeq (gs_0 - 1)\Gamma_2 \left[1 + \left(\frac{gs_0}{gs_0 - 1} \right)^2 \delta_3 \right] \\ \tau_p &\simeq \frac{T_2}{gs_0 - 1} \left[1 - \left(\frac{gs_0}{gs_0 - 1} \right)^2 \delta_3 \right] \\ t_0 &\simeq \frac{\tau}{g} + \frac{T_2}{2(gs_0 - 1)} \ln \left| \frac{2}{\delta_3} \left(1 - \frac{1}{gs_0} \right)^2 \right| \quad (78)\end{aligned}$$

Although the parameter δ_3 is small, it cannot be neglected, since its value is crucial for defining the delay time t_0 . If $\delta_3 \rightarrow 0$, then $t_0 \rightarrow \infty$. The parameter δ_3 , according to the notation (70), is proportional to the dynamic broadening width Γ_3 due to local spin fluctuations. As far as the latter fluctuations are the main cause of starting spin relaxation, it is not surprising that the related broadening defines the delay time.

From equation (72) it follows that the maximum of the coherent burst occurs at $t = t_0$, when

$$w(t_0) = \left(s_0 - \frac{1}{g} \right)^2, \quad s(t_0) = \frac{1}{g} \quad (79)$$

For longer times $t \gg t_0$, the superradiant signal exponentially diminishes, and the spin polarization returns to an almost inverted value,

$$w \simeq 4w(t_0)e^{-2\Gamma_p t}, \quad s \simeq -s_0 + \frac{2}{g} \quad (80)$$

The larger the spin-resonator coupling g , the more complete is the spin inversion. The effect of superradiant spin inversion can be employed for the ultrafast repolarization of nuclear targets used in scattering experiments.^{14,29}

The shape of a superradiant pulse, described by $w(t)$ in equation (72), is in very good agreement with experiments.¹¹⁻¹³ Thus, the measured signal, presented in Figure 2, ideally fits the calculated function $w(t)$, as is discussed in the papers.^{11,12} A concrete relation between the measured intensity of the signal and $w(t)$ is explained in Section 10.

It is worth emphasizing that the radiation intensity and duration time of the studied pulse have the properties typical of a superradiant burst. To illustrate this, it is sufficient to recall that the initial inverted spin polarization $s_0 = N_+/N$ is the ratio of the number of inverted spins to their total number in the sample. Inverted spins play the role of radiators, whose number is N_+ . For large spin-resonator coupling $g \gg 1$, one has $w(t_0) \sim s_0^2$ and $\tau_p \sim 1/s_0$, which is clear from the consideration above. Therefore

$$w(t_0) \sim N_+^2, \quad \tau_p \sim N_+^{-1}$$

which is characteristic of superradiance.

When there is no constant pumping by means of dynamic nuclear polarization, there appears one dominant superradiant burst given by equation (72). In an inhomogeneous sample, after the first burst, secondary maser oscillations can arise, whose accurate description requires numerical investigation.^{15-17,30-32}

It is interesting to mention that the signals of nuclear spin echo can also be essentially amplified by the presence of a resonant electric circuit coupled with a spin system, which has been observed in experiment.³³

8 PULSING SUPERRADIANCE

Another regime of spin superradiance can be achieved if the inversion of nuclear spins is constantly supported by a pumping mechanism, for instance, by dynamic nuclear polarization. Then, a series of superradiant bursts can be produced, as is experimentally observed.⁸⁻¹⁰ Such a regime, with a series of superradiant pulses that may repeatedly arise during a rather long time, can be termed pulsing superradiance. The theoretical description of this regime is based on the evolution equations (49) and (50), which require numerical computations.^{17,22,24} However, for the late stage, when $t \gg T_2, \tau$, and the system is close to a stationary state, it is possible to solve the problem analytically.

At the late stage, when $t \gg \tau$, the coupling function (42) becomes $\alpha = g\Gamma_2$. As is explained in Section 5, the resonator thermal noise can always be neglected, i.e., $\beta \rightarrow 0$. When there are no strong external transverse fields, then $v_1 \rightarrow 0$ and $v_2 \rightarrow 0$. For simplicity, the dynamic broadening width Γ_3 can also be neglected as compared to a large $g\Gamma_2$. Then the evolution equations (49) and (50) can be written as a two-dimensional dynamical system

$$\frac{dw}{dt} = v_1, \quad \frac{ds}{dt} = v_2 \quad (81)$$

with the velocity fields

$$v_1 = -2\Gamma_2(1 - gs)w, \quad v_2 = -g\Gamma_2w - \Gamma_1^*(s - \zeta) \quad (82)$$

In the presence of dynamic nuclear polarization, Γ_1^* is a pumping rate and $\zeta > 0$ is a pumping parameter.

An accurate theoretical analysis of (81) is given below. The velocity fields are taken in the simplified form (82). This is done for pedagogical reasons, in order not to become entangled in cumbersome formulas, but for emphasizing the principal ideas and techniques on which such an analysis is based. Using the same methods, one could accomplish an analysis of the evolution equations (49) and (50), including the dynamic broadening and external transverse fields, which would result in much more intricate equations.

An important quantity characterizing local stability of motion is the local expansion rate³⁴

$$\Lambda(t) \equiv \frac{1}{t} \text{Re} \int_0^t \text{Tr} \hat{X}(t') dt' \quad (83)$$

whose definition involves the Jacobian expansion matrix $\hat{X}$ which in this case is

$$\hat{X}(t) \equiv \begin{bmatrix} \frac{\partial v_1}{\partial w} & \frac{\partial v_1}{\partial s} \\ \frac{\partial v_2}{\partial w} & \frac{\partial v_2}{\partial s} \end{bmatrix}$$

If, at the moment t , the rate (83) is positive, $\Lambda(t) > 0$; this means that the phase volume of the dynamical system

expands, while if $\Lambda(t) < 0$, then the phase volume contracts. The eigenvalues of the expansion matrix $\hat{X}$ are the local characteristic exponents

$$X^\pm = -\frac{1}{2} \left\{ \Gamma_1^* + 2\Gamma_2(1 - g\zeta) \pm \sqrt{[\Gamma_1^* - 2\Gamma_2(1 - g\zeta)]^2 - 8g^2\Gamma_2^2 w} \right\}$$

whose real parts define the local Lyapunov exponents

$$\lambda^\pm(t) \equiv \text{Re} X^\pm(t)$$

The signs of the latter show whether the motion at the moment t is stable or not.

In the theory of dynamical systems,³⁵ one usually considers asymptotic stability related to the limit $t \rightarrow \infty$. The stationary, or fixed, points are given by the zeros of the velocity fields. The equations $v_1 = v_2 = 0$, with the velocities (82), yield two stationary solutions; one fixed point is

$$w_1^* = 0, \quad s_1^* = \zeta \quad (84)$$

and another is

$$w_2^* = \frac{\Gamma_1^*}{g^2\Gamma_2} (g\zeta - 1), \quad s_2^* = \frac{1}{g} \quad (85)$$

As is clear, among several solutions, the only values that make sense are in the region of validity of the considered functions. This region, as follows from equations (22) and (23), is limited by the inequalities

$$0 \leq w \leq 1, \quad -1 \leq s \leq 1$$

Thence, it is evident that the fixed point (85) may make sense only if $g\zeta \geq 1$. When $g\zeta = 1$, both fixed points (84) and (85) coincide. On the manifold of system parameters, the value $g\zeta = 1$ is termed a bifurcation point.

Because of the existence of two stationary solutions, the limit

$$\Lambda^* \equiv \lim_{t \rightarrow \infty} \Lambda(t) = \text{Re} \lim_{t \rightarrow \infty} \text{Tr} \hat{X}(t)$$

of the local expansion rate (83), for which $\Lambda^* = \lambda^+ + \lambda^-$, with the Lyapunov exponents

$$\lambda^\pm \equiv \text{Re} \lim_{t \rightarrow \infty} X^\pm(t)$$

possesses two different values. The local expansion rates at the first and second fixed points, respectively, are

$$\Lambda_1^* = -\Gamma_1^* - 2\Gamma_2(1 - g\zeta), \quad \Lambda_2^* = -\Gamma_1^* \quad (86)$$

According to the principle of minimal expansion,³⁴ the smaller the local expansion rate, the more stable is a dynamic state. The values (86) show that when $g\zeta < 1$, the fixed point (84) is more stable, while when $g\zeta > 1$, the stationary solution (85) becomes more stable.

The limits $X^\pm \equiv \lim_{t \rightarrow \infty} X^\pm(t)$ of the characteristic exponents, at the corresponding fixed points, are

$$\begin{aligned} X_1^+ &= -\Gamma_1^*, & X_1^- &= -2\Gamma_2(1 - g\zeta) \\ X_2^\pm &= -\frac{\Gamma_1^*}{2} \left[1 \pm \sqrt{1 - 8\frac{\Gamma_2}{\Gamma_1^*} (g\zeta - 1)} \right] \end{aligned} \quad (87)$$

The related real parts $\lambda^\pm = \text{Re} X^\pm$ define the Lyapunov exponents. Analyzing equation (87) yields the following classification of the fixed points (84) and (85).

When $g\zeta < 1$, then the Lyapunov exponents for the stationary solution (84) are negative, $\lambda_1^\pm < 0$. This says that the fixed point (84) is a stable node. For the stationary solution (85), one has $\lambda_2^+ < 0$ but $\lambda_2^- > 0$, which means that the fixed point (85) is a saddle. Hence, for $g\zeta < 1$, spin dynamics tends to the stationary solution (84). The relaxation rates are given by $\lambda_1^\pm = X_1^\pm$ defined in equation (87), from which it follows that the spin motion is incoherent.

In the case $g\zeta = 1$, the stationary solution is unique, since the fixed points (84) and (85) coincide. The related Lyapunov exponents are also the same: $\lambda_1^+ = \lambda_2^+ < 0$, $\lambda_1^- = \lambda_2^- = 0$. The value $g\zeta = 1$ is associated with a bifurcation point.

With the increasing pumping, when

$$1 < g\zeta < 1 + \frac{\Gamma_1^*}{8\Gamma_2},$$

one gets $\lambda_1^+ < 0$, $\lambda_1^- > 0$, while $\lambda_2^\pm < 0$. This indicates that the features of the fixed points have been changed — the fixed point (84) is now a saddle, while that of equation (85) has turned to a stable node. For realistic nuclear spins, $\Gamma_1^* \ll \Gamma_2$. Therefore, the considered region of $g\zeta$ is very narrow. The relaxation rates are close to $\lambda_2^\pm \approx -\frac{1}{2}\Gamma_1^*$; hence the spin motion is incoherent. The coherence intensity w_2^* , given in equation (85), although not zero exactly, but, since $\Gamma_1^* \ll \Gamma_2$ and $g > 1$, is very small (not much differing from zero).

Increasing the pumping further, so that

$$g\zeta > 1 + \frac{\Gamma_1^*}{8\Gamma_2}$$

changes the picture qualitatively. Then the fixed point (84) continues to be a saddle, since $\lambda_1^+ < 0$, $\lambda_1^- > 0$, but the fixed point (85) turns into a stable focus, as far as its characteristic exponents become complex,

$$X_2^\pm = -\frac{\Gamma_1^*}{2} \pm i\omega_\infty \quad (88)$$

with the asymptotic frequency

$$\omega_\infty \equiv \frac{\Gamma_1^*}{2} \sqrt{8\frac{\Gamma_2}{\Gamma_1^*} (g\zeta - 1) - 1} \quad (89)$$

This is the regime of pulsing spin superradiance, when there appears a long series of superradiant bursts lasting about the time $T_1^* = (\Gamma_1^*)^{-1}$. At the intermediate stage, this pulsing is not periodic, but becomes approximately periodic as time increases. The asymptotic frequency (89) defines the time interval $T_\infty \equiv 2\pi/\omega_\infty$ between superradiant pulses at the late stage, when the spin evolution is close to the stationary solution (85). This interpulse time for sufficiently strong pumping, with $g\zeta \gg 1$, is

$$T_\infty \equiv \frac{2\pi}{\omega_\infty} \simeq \pi \sqrt{\frac{2T_1^* T_2}{g\zeta}} \quad (90)$$

The time (90), by varying the related parameters, can be varied widely. For example, keeping in mind the parameters

typical of the proton spins,^{11–13} one has $\Gamma_0 = 2.85 \times 10^4$ Hz, $\omega_0 = 2.675 \times 10^8$ Hz, $\Gamma_2 = 1.18 \times 10^5$ Hz. With the quality factor $Q = 100$, the ringing width is $\gamma = 1.34 \times 10^6$ Hz. The spin-resonator coupling (67) is $g = 48$. For the pumping characteristics $\zeta = 1$ and $\Gamma_1^* = 10$ Hz, the interpulse time (90) is $T_\infty = 0.59 \times 10^{-3}$ s. The number of pulses can be estimated as $T_1^*/T_\infty \sim 100$. A detailed description of the regime of pulsing spin superradiance, for arbitrary times $t > 0$, can be accomplished with the help of numerical calculations.^{17,22,24} The phenomenon of pulsing spin superradiance may be employed for creating pulsing spin masers.²²

A regime, similar to pulsing spin superradiance, can also be realized without dynamic nuclear polarization. For this purpose, one could change the experimental setup used for realizing the transient spin superradiance as follows. In the latter regime, as is described in Section 7, if the spin-resonator coupling g is sufficiently strong, a sharp superradiant burst occurs at the delay time t_0 . After the time $t_0 + \tau_p$, the spin polarization, according to equation (80), becomes practically inverted, provided $g \gg 1$. If at this moment, one inverts the static magnetic field B_0 or acts on spins by a resonant π -pulse, or just turns the sample 180° about an axis perpendicular to B_0 , then again a strongly nonequilibrium state of almost completely inverted spins is prepared. After the time t_0 , counted from the moment when the newly inverted state is created, another superradiant burst will arise. Then, one could again either invert the static magnetic field or invert the magnetization by a resonant π -pulse, or turn the sample to arrange a novel nonequilibrium inverted state of spins. After this, one more superradiant burst will appear. Such a procedure can be repeated as many times as necessary for producing a required number of sharp superradiant pulses. The regime achieved may be named *punctuated spin superradiance*. The principal difference of this regime from the pulsing spin superradiance is the possibility of controlling the number of pulses as well as the interpulse time. The term *punctuation* here implies the possibility of varying the time intervals between pulses and to form groups of pulses, containing different numbers of the latter. In that way, it is feasible to compose a code, similar to the Morse alphabet. Hence, punctuated spin superradiance can be used for processing information, which may be employed, for instance, in quantum computers.

9 HYPERFINE INTERACTIONS

Real solids, in addition to nuclei, always contain electrons. It is therefore important to understand the influence of hyperfine spin-spin interactions between nuclei and electrons on nuclear spin superradiance.

A system of nuclear and electronic spins is described by the Hamiltonian

$$\hat{H} = \hat{H}_{\text{nuc}} + \hat{H}_{\text{ele}} + \hat{H}_{\text{hyp}} \quad (91)$$

in which the nuclear term $\hat{H}_{\text{nuc}}$ is given by equation (1). The electronic spin Hamiltonian is

$$\hat{H}_{\text{ele}} = -\frac{1}{2} \sum_{i \neq j} J_{ij} \hat{\mathbf{S}}_i \cdot \hat{\mathbf{S}}_j + \hbar \gamma_e \sum_i \mathbf{B} \cdot \hat{\mathbf{S}}_i \quad (92)$$

where J_{ij} is an exchange interaction potential, $\hat{\mathbf{S}}_i$ is an electron spin, and γ_e is the electron magnetogyric ratio. The part of the Hamiltonian (91) describing hyperfine interactions is

$$\hat{H}_{\text{hyp}} = A \sum_i \hat{\mathbf{S}}_i \cdot \hat{\mathbf{I}}_i + \frac{1}{2} \sum_{i \neq j} \sum_{\alpha\beta} A_{ij}^{\alpha\beta} \hat{S}_i^\alpha \hat{I}_j^\beta \quad (93)$$

Here the first term is the Fermi contact hyperfine interaction of nuclei with s -electrons, characterized by the energy

$$A = \frac{8\pi}{3} \hbar^2 \gamma_e \gamma_n |\psi(0)|^2 \quad (94)$$

where $\psi(\mathbf{r})$ is the electron wave function. The second term in equation (93) presents the dipolar hyperfine interactions, with

$$A_{ij}^{\alpha\beta} = -\hbar^2 \frac{\gamma_e \gamma_n}{r_{ij}^3} (\delta_{\alpha\beta} - 3n_{ij}^\alpha n_{ij}^\beta) \quad (95)$$

Consideration of the problem with the Hamiltonian (91) can be accomplished by employing the same methods detailed in the previous sections. The main technical difference is that the consideration becomes more cumbersome, as now it is necessary to deal with six evolution equations for spins, three of which are nuclear spins and three are electronic spins.^{23,24} The seventh equation is the Kirchhoff equation (19), in which the magnetization density is now a sum

$$M_x = \frac{\hbar}{V} \sum_i (\gamma_n \langle \hat{I}_i^x \rangle - \gamma_e \langle \hat{S}_i^x \rangle) \quad (96)$$

of the terms due to nuclear and electronic spins. The evolution equations can be again solved by invoking the scale separation approach.^{19–21,24,27} The most important conclusions resulting from the presence of hyperfine interactions are as follows.

Local spin fluctuations of electrons lead to the increase of the nuclear dynamic broadening, which results in the sum

$$\tilde{\Gamma}_3 = \Gamma_3 + \Gamma'_3 \quad (97)$$

of the widths caused by nuclear dipolar interactions, Γ_3 , and by electron-nuclear hyperfine interactions, Γ'_3 . The relation between these widths is given by the ratio

$$\frac{\Gamma'_3}{\Gamma_3} = \frac{\rho_e \mu_e}{\rho_n \mu_n} \quad (98)$$

in which ρ_e and ρ_n are the electron and nuclear densities, while $\mu_e \equiv \hbar \gamma_e S$ and $\mu_n \equiv \hbar \gamma_n I$ are the electron and nuclear magnetic moments, respectively. When the electron and nuclear densities are close to each other, then, because $\mu_e/\mu_n \sim 10^3$, the ratio (98) can be large compared to unity. Therefore, the width (97) can be essentially increased by the hyperfine interactions. This results in the shortening of the delay time t_0 of a superradiant burst, as well as in shortening the pulse time τ_p .

In the electronic subsystem, long-range magnetic order may appear due to the exchange interaction of electronic spins. If so, the NMR frequency shifts to the value

$$\omega_n = \omega_0 + \frac{A}{\hbar} S m_z \quad (99)$$

where m_z is the z -projection of the average electronic magnetization normalized to unity and A is the parameter (94). Then, the frequency (99) will enter all formulas instead of ω_0 .

Long-range magnetic order of electrons leads to the renormalization of the coupling with the resonator according to the rule

$$\tilde{g} = g \left(1 + \frac{\rho_e \mu_e A}{\rho_n \mu_n \hbar \omega_n} m_z \right) \quad (100)$$

This may result because of the large ratio $\mu_e/\mu_n \sim 10^3$ in an essential increase of the coupling (100), as compared to g . The electronic subsystem plays the role of an additional resonator, which enhances the effective coupling of nuclear spins with the resonant electric circuit.²⁴

10 RADIATION INTENSITY

To complete the treatment, it is worth emphasizing once again why this phenomenon can be called spin superradiance. An ensemble of coherently moving nuclear spins, as is clear, generates magnetodipole radiation with total intensity

$$I(t) = \frac{2}{3c^3} |\dot{\mathbf{M}}(t)|^2 \quad (101)$$

where

$$\mathbf{M}(t) = \hbar \gamma_n \sum_i \langle \mathbf{I}_i(t) \rangle$$

is the total magnetization of nuclei. The quantity of interest is the radiation intensity averaged over fast oscillations. For the intensity (101), this yields

$$\bar{I}(t) = \frac{2}{3c^3} \mu_n^2 \omega_0^4 N^2 w(t) \quad (102)$$

where, as always, $\mu_n \equiv \hbar \gamma_n I$ is the nuclear magnetic moment. As is seen, the radiation intensity is proportional to the number of spins squared, which is characteristic of superradiance.

Although coherently moving spins do produce superradiance, the radiation intensity (102) is not high. At the peak of a superradiant burst, $w(t_0)$ is given by equation (79). For $g \gg 1$ and $s_0 \approx 1$, one has $w(t_0) \approx 1$. Then the maximal radiation intensity, for proton spins, with $\mu_n = 1.411 \times 10^{-26} \text{ J T}^{-1}$, $\omega_0 = 2.675 \times 10^8 \text{ Hz}$, and $N \approx 10^{23}$, is $\bar{I}(t_0) \approx 2.5 \times 10^{-5} \text{ W}$.

Despite such weak radiation intensity, it can be easily detected. This is because what is directly measured is the power of the current

$$P(t) = R j^2(t) \quad (103)$$

which is generated in a coil by the radiating spins. Using the relation of the induced current with the resonator magnetic field (14), one gets

$$j^2(t) = \frac{V_c}{4\pi L} H^2(t)$$

The field H can be found from equation (41). Setting $\beta = 0$ in this equation, i.e., neglecting thermal noise, and averaging over fast oscillations gives

$$\overline{H^2(t)} = \frac{2}{\gamma_n^2} \alpha^2(t) w(t)$$

Then, for the averaged current power (103), one finds

$$\bar{P}(t) = g \Gamma_2 I \hbar \omega N (1 - e^{-\gamma t})^2 w(t) \quad (104)$$

This expression contains, as compared to equation (102), an additional dependence on the feedback retardation. But for $t \gg \tau$, the radiation intensity (102) and the current power (104) differ one from another only by a numerical factor

$$\frac{\bar{P}(t)}{\bar{I}(t)} \simeq \frac{3g\Gamma_2\lambda^3}{16\pi^2\Gamma_0 V_c} = \frac{3Q\lambda^3}{8\pi^2 V_c} \quad (105)$$

in which $\lambda = 2\pi c/\omega$ is the radiation wavelength. For an NMR frequency $\omega = 2.675 \times 10^8 \text{ Hz}$, one has $\lambda = 0.71 \times 10^3 \text{ cm}$. The factor (105) can reach rather large values. Thus, if $Q = 100$ and $V_c = 10 \text{ cm}^3$, this factor is of the order of 10^8 . This is why even a low radiation intensity can be easily measured.

11 APPLICATIONS

Nuclear spin superradiance is collective spontaneous radiation by nuclear spins at the frequency of nuclear magnetic resonance. This phenomenon is an analog of atomic superradiance occurring at optical frequencies. Being a novel coherent phenomenon at NMR frequencies, it may find various applications.

1. *Investigation of materials characteristics.* Spin relaxation in materials is commonly employed for studying relaxation parameters describing intrinsic properties of matter. Nuclear spin superradiance is accomplished by a self-organized coherent spin relaxation, which is drastically different from other types of spin relaxation. Another kind of relaxation may provide additional information on the properties of materials. Thus, the main mechanism originating pure spin superradiance is the existence of local spin fluctuations caused by the interaction of nuclear spins with each other, by means of dipolar forces, and with electronic spins, through hyperfine forces. Therefore, studying specific features of pure spin superradiance provides information about these local fluctuations.
2. *Fast repolarization of targets.* The relaxation of nuclear spins, in the process of superradiance, happens much faster than the usual spin-dephasing time T_2 . If the initial spin polarization is sufficiently high and the spin-resonator coupling is sufficiently strong, spins, after a superradiant burst, change their orientation becoming almost completely inverted. Such an ultrafast inversion of spins can be employed for quick repolarization of polarized solid-state targets used in scattering experiments.
3. *Construction of spin masers.* A superradiant spin system is a source of coherent radiation at radio frequencies. Being a source of coherent radiation, it is analogous to

lasers operating at optical frequencies. Spin masers could find applications similar to those of optical lasers. A spin maser can function in a transient regime, emitting a single burst typical of pure or triggered spin superradiance, and it can also work in a lasting regime based on pulsing spin superradiance.

4. *Creation of sensitive detectors.* Spin superradiance can be triggered by a very weak external pulse of intensity corresponding to w_0 . The latter depends exponentially on the delay time t_0 . Therefore, measuring the delay time of a superradiant burst provides an accurate evaluation of the triggering intensity. Then, triggered spin superradiance may serve as a sensitive mechanism for detecting weak external signals.
5. *Methods of information processing.* In the regime of punctuated superradiance, the intervals between superradiant bursts as well as the number of pulses can be regulated. This makes it feasible to compose a kind of Morse Code alphabet and then to develop a technique of processing information. Such a method of information processing could be used in quantum computers.

In conclusion, it is necessary to note that the developed theory, as well as possible applications, are appropriate not only for nuclear spins but, in general, for any spin system. For instance, all this can be immediately extended to electronic spins. A related phenomenon is *electron spin superradiance*. Other types of materials could be the so-called molecular magnets formed of magnetic molecules. The latter often have high spins, thus possessing several quantum transitions. In that case, the resonant electric circuit has to be tuned to one of the admissible transition frequencies. The resulting effect would be *molecular spin superradiance*, whose intensity could be much higher than that of nuclear spins. Nuclear spin superradiance is just a representative from a class of phenomena called *spin superradiance*. These phenomena, being realized with different materials, should exhibit a rich variety of specific features that could be not only interesting but also useful for various applications.

1 INTRODUCTION

The solid hydrogens (H_2 and D_2) are the simplest molecular solids that exist in Nature, and a detailed understanding of their many body properties is of special interest because the rotational degrees of freedom are those of quantum rotors and their behavior at low temperatures can be understood from considerations of first principles. The interaction Hamiltonians are well known and studies of the ordering of the molecular orientations have revealed interesting new regimes of collective phenomena. NMR has provided one of the most sensitive tools for probing the orientational degrees of freedom of the quantum rotors because of the intimate relationship between the constraints on the molecular nuclear spin wave function and the rotational (or orbital) degrees of freedom that results in the existence of distinct molecular species: the *ortho* and *para* modifications.

All the homonuclear isotopes of molecular hydrogen (H_2 , D_2 , and T_2) have distinct molecular species;¹ i.e. *ortho* and *para* modifications, resulting from the requirements of symmetry considerations that apply to the molecular wave function. For H_2 and T_2 , the nuclei are fermions with nuclear spin $I = \frac{1}{2}$, and the requirement that the total molecular wave function be antisymmetric can be satisfied in two ways: (1) *ortho*- H_2 (or T_2) for which the nuclear spin wave function for the molecule is symmetric with total nuclear spin $I_T = 1$ and for which the molecular orbital angular wave function is antisymmetric with orbital angular momentum J odd ($J = 1, 3, 5, \dots$); and (2) *para*- H_2 (or T_2) for which the nuclear spin wave function is antisymmetric ($I_T = 0$) with J even ($J = 0, 2, 4, \dots$). For D_2 , the nuclei are bosons with nuclear spin $I = 1$, and the requirement that the total molecular wave function be symmetric can also be satisfied in two distinct ways: (1) *para*- D_2 with total nuclear spin $I_T = 1$ and orbital angular momentum J odd; (2) *ortho*- D_2 with the nuclear spin wave function symmetric ($I_T = 0$ or 2) and with orbital angular momentum J even. Table 1 summarizes the symmetry properties of these different molecular species.

The aspect of the molecular species of the hydrogens that make them unique compared with other (heavier) homonuclear diatomic molecules (such as N_2) is that the separation of the rotational energy levels is very large compared with the

anisotropic interactions between the molecules. The rotational kinetic energies are given by $E_J = B_J J(J + 1)$ with $B_J = \hbar^2/(2mr^2)$, where r is the intermolecular separation and $B_J = 85.6$ K for H_2 (43.2 K for D_2), and the $J = 1$ and $J = 2$ rotational states are 171 K and 510 K above the $J = 0$ ground state, respectively, for H_2 (and 86 K and 257 K, respectively, for D_2). We therefore only need to consider the lowest rotational states $J = 1$ and $J = 0$ in the solid hydrogens. Furthermore, the anisotropic interactions between the molecules that can admix different J states are very weak ($V_{\text{aniso}} \simeq 1$ K). J is therefore a good quantum number to first order and we may consider the $J = 1$ species (*ortho*- H_2 (or T_2) and *para*- D_2) as quantum rotors.

The conversion of $J = 1$ molecular species to the ground state ($J = 0$) is very slow because it is doubly forbidden; two symmetries need to be broken simultaneously, the symmetry of the nuclear wave function and that of the orbital wave function, in order to convert a $J = 1$ *ortho* molecule into a $J = 0$ molecule. In the pure solid this conversion is induced by the intermolecular magnetic interactions, and leads to a bimolecular rate constant of 1.9% per hour for H_2 (and 0.06% per hour for D_2). This rate is sufficiently slow that we may consider the *ortho* species as stable on the timescale of ordinary experiments. On the other hand, over a few weeks or months, the experimenter may explore a wide range of *ortho* concentrations continuously, simply by allowing a sample to age at constant low pressure. Alternatively, samples of essentially pure $J = 0$ species or pure $J = 1$ species can be prepared by special techniques, and solid mixtures of the full range of *ortho/para* concentrations studied by mixing the appropriate amounts of $J = 0$ species and $J = 1$ species in the gaseous state and solidifying the mixture. Pure $J = 0$ species are prepared by conversion on paramagnetic surfaces² (e.g. zeolites saturated with chromic oxide), and $J = 1$ species by selective adsorption on alumina.³

The behavior of the $J = 1$ quantum rotors (*ortho*- H_2 and *para*- D_2) can be studied directly by NMR.^{4,5} The total nuclear spin of these molecules is $I_T = 1$ and the intramolecular interactions do not average to zero if the molecules have a preferred orientation in space. A fine structure is observed in the absorption spectrum and this can be used to determine the quantum mechanical order parameters. Furthermore, the nuclear spin–lattice (T_1) and nuclear spin–spin (T_2) relaxation times depend on the fluctuation spectrum of the molecular orientations, and measurements of T_1 and T_2 can be used to determine the fundamental rotational excitations of the molecular rotors.

2 ORIENTATIONAL PARAMETERS AND NMR SPECTRA

The $J = 1$ molecules are not spherically symmetric; they have end-on symmetry and hence no permanent electric dipole moment, but they do have a small axial electric quadrupole moment Q . There is therefore a weak electrostatic quadrupole–quadrupole (EQQ) interaction between the molecules that depends on their relative orientations.⁶ At high temperatures the molecules are free to rotate, but at low temperatures the $J = 1$ molecules adopt mutual orientations to minimize their EQQ interactions. The EQQ interaction is short

2 ORTHO-PARA HYDROGEN AT LOW TEMPERATURE

Table 1 Molecular Species of Hydrogen Isotopes^a

	<i>ortho</i> -H ₂ (or T ₂)	(<i>para</i> -D ₂)	<i>para</i> -H ₂ (or T ₂)	(<i>ortho</i> -D ₂)
Angular momentum ^b	Odd $J = 1$	(Odd) ($J = 1$)	Even $J = 0$	(Even) ($J = 0$)
Total nuclear spin	Even $I_T = 1$	(Odd) ($I_T = 1$)	Odd $I_T = 0$	(Even) ($I_T = 0$ and 2)

^aThe terminology *ortho-para* refers to the total nuclear spin symmetry. The full molecular wave function must be odd (even) for molecular H₂ and T₂ (D₂), respectively. The total nuclear spin wave function: $|I_T m_T\rangle = \sum_{m_1 m_2} C_{m_1 m_2 m_T}^{I_1 I_2 I_T} |I_1 m_1\rangle |I_2 m_2\rangle$ where the $C_{m_1 m_2 m_T}^{I_1 I_2 I_T}$ are the Clebsch–Gordan coefficients, e.g. for *para*-H₂, $|00\rangle = 2^{-\frac{1}{2}} \{ |\frac{1}{2}, \frac{1}{2}\rangle |\frac{1}{2}, -\frac{1}{2}\rangle - |\frac{1}{2}, -\frac{1}{2}\rangle |\frac{1}{2}, \frac{1}{2}\rangle \}$.

^bHigher J states need not be considered for normal densities at low temperatures.

range and only nearest neighbor interactions need be considered. For an isolated pair the minimum energy configuration is a ‘T’ orientation (Figure 1) with the quadrupoles mutually perpendicular.

For a simple two-dimensional square lattice, a simple antiferro-orientational array is the minimum energy configuration [Figure 2(a)] and this is stable with respect to substitution by a spherical ($J = 0$) molecule. For other lattices, however, the molecules cannot all be oriented so that each neighboring pair is in the ‘T’ configuration. This is illustrated in Figure 2(b) for a triangular lattice for which the lowest total energy configuration is a herring-bone arrangement. This arrangement is not stable with respect to substitution by ‘inert’ $J = 0$ molecules. This topological incompatibility between the configuration of the lowest energy pair and the geometry of the crystal lattice structure is a particularly striking example of the phenomenon of ‘frustration’ that is a key feature of the spin glasses and many other glass formers. The effect of substitutional disorder on frustrated systems can be studied in depth using *ortho-para* mixtures because the substitution is close to ideal (a $J = 1$ molecular species being replaced by a $J = 0$ species, with no other change) and the order parameters and the molecular dynamics can be determined directly from NMR studies.

The distinction between the ordering in the familiar magnetic systems and the diatomic molecular systems is that for the former one needs in most cases to consider only the dipole moments $\langle S_x \rangle_k$, $\langle S_y \rangle_k$, and $\langle S_z \rangle_k$ of a spin S at lattice site k , whereas for the $J = 1$ rotors we need in general to specify the quadrupole moments $\langle J_\epsilon J_\phi \rangle_k$ as well as the vectorial moments $\langle J_\epsilon \rangle_k$. Only five of the quadrupole moments are independent variables; ϵ and ϕ represent one of the Cartesian components (x, y, z) of a local reference frame.

In the absence of any interactions that break time-reversal symmetry, the orbital angular momentum is quenched, i.e. the $\langle J_\epsilon \rangle_k$ vanish for all ϵ . Five parameters are needed to describe fully the rotational degrees of freedom, and the natural choice is to select as local reference axes (x, y, z) the principal axes

Figure 1 Configurations of a pair of interacting axial quadrupoles for (a) minimum, and (b) maximum energy

Figure 2 Schematic representation of the effect of substitutional disorder on quadrupolar arrays for (a) nonfrustrated, and (b) frustrated configurations

of the quadrupolar tensor with elements:

$$q_{\epsilon\phi} = \langle \frac{1}{2} J^2 \delta_{\epsilon\phi} - \frac{3}{4} (J_\epsilon J_\phi + J_\phi J_\epsilon) \rangle \quad (1)$$

In the local principal axes frame, the off-diagonal elements, $q_{xy} = q_{yz} = \dots = q_{zx} = 0$, and the only intrinsic quadrupolar order parameters are: (1) the *alignment*

$$\sigma_k = Q_{zz} = \langle 1 - \frac{3}{2} J_z^2 \rangle_k \quad (2)$$

and (2) the *eccentricity*

$$\eta_k = \langle J_x^2 - J_y^2 \rangle_k \quad (3)$$

The five order parameters are the three local reference axes (specifying the direction of the molecular orientation), and the two quadrupolar order parameters σ and η (which describe the degree of alignment along those axes).

The strong positivity conditions on the single particle density matrix (i.e. that the eigenvalues be positive definite) limit the allowed values of σ and η to the bounds defined by

$$\frac{1}{3} + \frac{2}{3}\sigma \geq 0; \quad \frac{1}{3} - \frac{1}{3}\sigma \pm \frac{1}{2}\eta > 0 \quad (4)$$

Not all the allowed pairs (σ, η) in this range are physically distinguishable, however, since we are free to relabel the axes,

and by convention we choose axes such that $\sigma \geq \frac{1}{2}\eta > 0$. There are two single particle ‘pure’ states: ($\sigma = 1, \eta = 0$), corresponding to a ground state $|J_z = 0\rangle$ and ($\sigma = \frac{1}{2}, \eta = \pm 1$), corresponding to the ground state $|J_z = \pm 1\rangle$. States intermediate between these ‘pure’ states can be realized in the many-particle system; this feature was first observed in NMR studies of *ortho*-*para* hydrogen mixtures.^{4,7}

The ability to study the orientational order parameters by NMR arises from the fact that the intramolecular nuclear dipole-dipole interaction $\hat{\mathcal{H}}_{DD}$ between the two nuclei of a given molecule depends directly on the order parameters. This can be seen by expressing $\hat{\mathcal{H}}_{DD}$ in terms of products of irreducible tensorial operators $\hat{T}_{LM}$ in the manifold $J = 1$ with the corresponding nuclear spin operators $\hat{N}_{LM}$ in the manifold $I = 1$:

$$\hat{\mathcal{H}}_{DD} = \hbar D \sum_M \hat{T}_{LM} \hat{N}_{2M}^\dagger \quad (5)$$

The $\hat{T}_{LM}$ and $\hat{N}_{LM}$ transform in the same manner as the spherical harmonics Y_{LM} and are given in Table 2, with $D = 173.06$ kHz for H_2 (2.74 kHz for D_2). [For D_2 there is an additional intramolecular term arising from the interaction of the nuclear electric quadrupole moment with the local electric field gradient. This interaction Hamiltonian transforms identically to the form given by equation (5) but with D replaced by $D_Q = 22.50$ kHz.]

The dipolar interaction term given by equation (5) results in a small perturbation of the nuclear Zeeman energy levels. For high magnetic fields $\mathbf{B}_0$ lies along the z axis, and the nuclear Zeeman interaction

$$\hat{\mathcal{H}}_Z = \gamma \hbar \hat{\mathbf{I}} \cdot \mathbf{B}_0 \quad (6)$$

results in three equally spaced Zeeman levels for $I_z = 1, 0, -1$ (Figure 3) with energy spacings $\Delta E_{10} = \Delta E_{-10} = \hbar \omega_L$, where ω_L is the nuclear Larmor frequency. If $\hat{\mathcal{H}}_{DD}$ is motionally averaged to zero (corresponding to isotropic molecular reorientation on a timescale that is short compared to D^{-1}), only a single NMR absorption line is observed at the Larmor frequency. If the molecule has a preferred orientation, $\hat{\mathcal{H}}_{DD}$ does not average to zero and the transitions ΔE_{10} and ΔE_{-10} are no longer equal. $\hat{\mathcal{H}}_{DD}$ is treated as a perturbation of

Table 2 Irreducible Angular Momentum Operators $\hat{T}_{LM}$ (in manifold $J = 1$) and Nuclear Spin Operators $\hat{N}_{LM}$ (in the manifold $I = 1$)^a

	Tensorial operator, $\hat{T}_{LM}$	Tensorial operator, $\hat{N}_{LM}$
$L = 1$		
	$\hat{T}_{1,0} = 2^{-\frac{1}{2}} \hat{J}_z$	$\hat{N}_{1,0} = 2^{-\frac{1}{2}} \hat{I}_z$
	$\hat{T}_{1,\pm 1} = \mp \frac{1}{2} (\hat{J}_x \pm i \hat{J}_y)$	$\hat{N}_{1,\pm 1} = \mp \frac{1}{2} (\hat{I}_x \pm i \hat{I}_y)$
$L = 2$		
	$\hat{T}_{2,0} = 6^{-\frac{1}{2}} (3 \hat{J}_z^2 - \hat{J}^2)$	$\hat{N}_{2,0} = 6^{-\frac{1}{2}} (3 \hat{I}_z^2 - \hat{I}^2)$
	$\hat{T}_{2,\pm 1} = \mp \frac{1}{2} (\hat{J}_x \hat{J}_z + \hat{J}_z \hat{J}_x)$	$\hat{N}_{2,\pm 1} = \mp \frac{1}{2} (\hat{I}_x \hat{I}_z + \hat{I}_z \hat{I}_x)$
	$\hat{T}_{2,\pm 2} = \frac{1}{2} (\hat{J}_\pm)^2$	$\hat{N}_{2,\pm 2} = \frac{1}{2} (\hat{I}_\pm)^2$

^a $\hat{T}_{LM} = (-)^M \hat{T}_{L,-M}^\dagger$ and $\text{Tr}(\hat{T}_{LM} \hat{T}_{L'M'}^\dagger) = \delta_{LL'} \delta_{MM'}$; and similarly for the $\hat{N}_{LM}$.

Figure 3 Splitting of the NMR absorption line at ν_L into a doublet with $|\Delta\nu_k| = D \langle 1 - \frac{3}{2} J_z^2 \rangle_k$ for each molecule that is orientationally ordered

$\hat{\mathcal{H}}_Z$ and each molecule now contributes a doublet to the NMR spectrum with components at frequencies

$$\Delta\nu_k = \mp D \langle 1 - \frac{3}{2} J_z^2 \rangle_k \quad (7)$$

on either side of the Larmor frequency. Here, the brackets $\langle \rangle$ indicate averaging over all crystallite orientations with respect to the static field $\mathbf{B}$.

The average $\langle 1 - \frac{3}{2} J_z^2 \rangle_k$ is valid for a timescale that is long compared with D^{-1} , and the expectation value is evaluated with respect to the magnetic field axis and not the local symmetry axis with respect to which the local molecular order parameters are defined. Transforming to the local molecular frame, we find that

$$\Delta\nu_k = \mp D [-\sigma_k P_2(\cos \alpha_k) + \frac{3}{4} \nu_k \sin 2\alpha_k \cos 2\beta_k] \quad (8)$$

where (α_k, β_k) are the polar angles defining the orientation of the applied magnetic field with respect to the local molecular axes. The analysis of the spectra has been carried out assuming local axial symmetry $\eta = 0$ for the molecular ordering, and while no inconsistency has been demonstrated for this assumption, it has not been established rigorously.

The majority of NMR experiments are carried out using powder samples, and the lineshapes calculated for a powder distribution with a fixed value of σ at each site yields the familiar Pake doublet lineshape (Figure 4). The intensities $I_{\pm 1,0}$ for the transitions ΔE_{10} and ΔE_{-10} are given by

$$I_{\pm 1,0}(\Delta\nu, \sigma) = \left[2\sqrt{3} D \sigma \left(1 \mp \frac{2\Delta\nu}{D\sigma} \right)^{1/2} \right]^{-1} \quad (9)$$

Figure 4 Pake doublet NMR absorption spectrum for the fixed value of molecular order parameter σ

The cusp singularities at $\Delta\nu = \mp \frac{1}{2}D\sigma$ correspond to molecules with $\alpha = \pi/2$, i.e. those molecules aligned in a plane normal to the applied magnetic field. The separation of the cusps provides a direct measure of the local molecular order parameters, and is thus used to study the collective ordering of the molecules as a function of temperature.

3 PHASE DIAGRAM OF SOLID ORTHO-PARA HYDROGEN MIXTURES

If the concentration of quadrupolar species ($J = 1$ molecules) is sufficiently high (>55% for H_2 and >59% for D_2), a long range periodic ordering of the molecular orientations is observed. At low temperatures the molecular alignments are ordered in a four-sublattice Pa_3 configuration on a fcc lattice (Figure 5), with the molecules aligned parallel to one of the four body diagonals in each sublattice. The local order parameters have the values $\sigma = 1$ at each site (when evaluated with respect to the local principal orientation axis in each sublattice). The transition to the ordered phase is first order (with a jump in the value of σ at the transition), and the transition triggers a lattice change from a hcp structure (the high-temperature phase) to a fcc lattice. Subsequent small thermal cycles above and below the transition temperature stabilize the cubic lattice, and one can observe the purely orientational order-disorder transitions on the fcc lattice. As the $J = 1$ concentration is lowered, the transition temperature is reduced, and the phase diagram calculated from first principles is in good qualitative agreement with experimental observations, but the theoretical values are consistently higher than the observed values by about 17%.^{8,9}

Below the critical concentration of $J = 1$ species (approximately 55% for H_2 and 59% for D_2), the long-range periodic ordering is lost. At low concentrations a new quadrupolar glass structure is observed. Experimental observations (NMR studies and heat capacity measurements) all indicate that the molecules

Figure 5 Pa_3 structure for molecular alignments in the fcc lattice

become frozen in a random configuration, with both the local molecular symmetry axes and the local alignments (the values of σ_k at each site) varying at random throughout the crystal. The tensorial order varies randomly from site to site in the glass state, as illustrated in Figure 6. The NMR spectra provide the strongest evidence for a glass phase from the appearance of a broad bell-shaped absorption line (Figure 7) rather than the Pake doublet lineshape which characterizes the periodic ordering.

Figure 6 Schematic representation of molecular ordering for (a) a planar section of the Pa_3 structure, and (b) the quadrupolar glass phase

Figure 7 Bell-shaped NMR absorption line in the quadrupolar glass phase calculated for a linear distribution of order parameters

The loss of periodic order in the dilute *ortho*-*para* mixtures is attributed to the introduction of disorder in a highly frustrated system. The combined effects of frustration and disorder are believed to be universal features of magnetic spin glasses, and the quantum rotor glasses provide a particularly interesting example for probing the properties of these systems. The interactions are short range and well understood, the introduction of the disorder is especially clean, and the local order parameters and molecular dynamics can be studied directly by NMR.

The transitions from the high-temperature phase to the glass state are not abrupt. The molecular rotational fluctuations have been determined from measurements of the nuclear spin-lattice relaxation rates,¹⁰⁻¹² showing that the characteristic molecular fluctuation rates increase continuously but rapidly over a relatively small temperature range (Figure 8).

Figure 8 Temperature dependence of the nuclear spin-lattice relaxation times T_1 in the glass phase. τ_Q are the characteristic molecular reorientational times deduced from T_1

Figure 9 Phase diagram for orientationally ordered phases of solid hydrogen

The phase diagram for *ortho*-*para* H_2 mixtures deduced from NMR studies is shown in Figure 9. The solid and broken lines indicate first-order transitions to the periodic antiferro-orientational Pa_3 structure, and the hatched region corresponds to the continuous transition to the glass state. The behavior of the molecular orientations at very low temperatures below the percolation concentration (15%) has not been explored in detail. At very low $J = 1$ concentrations, indirect anisotropic long-range interactions are expected to dominate, and could lead to new behaviors.

4 MOLECULAR DYNAMICS AND LOW ENERGY EXCITATIONS

The molecular dynamics in the quadrupolar glass phase have been studied at low temperatures using stimulated echo techniques.¹³⁻¹⁵ A preparatory two pulse sequence is used to store both nuclear polarizations (I_z) and nuclear spin alignments (I_z^2) in a given initial state. After a waiting period, a third pulse is used to determine the changes in the molecular orientations during the waiting time. The intramolecular nuclear spin-spin interactions $\hat{H}_{DD}$ determine the evolution during the waiting period, and because $\hat{H}_{DD}$ depends directly on the order parameters σ_k , slowly varying changes in the molecular orientations can be detected using this method.

A logarithmic decay is observed for the stimulated echoes over a wide range of conditions, and this decay has been analyzed quantitatively in terms of a spectrum of low energy excitations corresponding to reorientations of clusters of molecules in the glass state. The spectrum of excitations deduced from the NMR measurements has been used to analyze the temperature dependence of the heat capacities determined from independent thermodynamic measurements.^{16,17} An excellent fit to the thermodynamic data was obtained without any adjustable parameters, providing one of the most convincing demonstrations of the fundamental

nature of the glass state: a freezing of the molecular alignments in local short-range ordered clusters with a broad spectrum of collective excitations corresponding to molecular reorientations in the clusters.

The systematic NMR studies of solid *ortho/para* mixtures of hydrogen and deuterium have established the existence of a new quadrupolar glass state for dilute samples of quantum rotors. The local order parameters are tensorial rather than vectorial as in the conventional orientational glass and spin glass systems. The *ortho/para* mixtures have served as a test case for the study of glass formers in general because the interactions are well understood and the order parameters can be studied directly using NMR. Further studies on two-dimensional films and monolayers will provide new information about the effect of dimensionality on highly frustrated systems, and could reveal new collective behaviors for two-dimensional assemblies of quantum rotors at low temperatures.

1 INTRODUCTION

In the context of this article, the term ‘optical pumping’ refers to the creation of large, nonequilibrium nuclear spin polarizations by irradiation of a sample at optical wavelengths. Significant optical pumping effects have been reported in several classes of samples, including organic molecular crystals,¹ mixtures of noble gases and alkali metal vapors,² biological photosynthetic systems,^{3–5} and inorganic semiconductors.^{6,7} Optical pumping of nuclear spin polarization in a semiconductor was first described by George Lampel in 1968, for the case of crystalline Si.⁶ In Lampel’s original experiments, Si samples were irradiated with an arc lamp at 77 K and fields of 0.16 T or less, and ²⁹Si polarization was measured by direct NMR detection. Optical pumping was observed with both circularly polarized and unpolarized light. Lampel’s observations were explained in terms of photoexcitation of conduction electrons with nonequilibrium electron spin polarization and subsequent dynamic polarization of hyperfine-coupled nuclear spins. Although the magnitude of the ²⁹Si polarizations in Lampel’s experiments were only of order 10^{–5}, these experiments set the stage for later optical pumping experiments in which polarizations of order 10% have been achieved.^{8,9}

Following Lampel’s experiments and other optical pumping experiments on Si,^{10–12} attention shifted to III–V semiconductors, principally GaAs and AlGaAs, and to optical detection

of the NMR spectra.^{13–17} These and other recent experiments have been performed at temperatures on the order of 10 K or lower. In optically detected NMR (ODNMR) experiments, the large nuclear spin polarization created by optical pumping exerts a strong average hyperfine field on the photoexcited electrons, which can then affect the evolution or steady-state of the photoexcited electron spin polarization. In analogy to the Hanle effect,^{18,19} the optically pumped nuclear hyperfine field can be made to reduce the degree of circular polarization of the photoluminescence that accompanies electron-hole recombination when radio-frequency (rf) fields are applied near the NMR lines. The original ODNMR experiments on semiconductors^{13–17} were carried out on bulk materials and with continuous wave (cw) rf irradiation (i.e., frequency domain ODNMR). Recent ODNMR experiments have focussed on semiconductor thin films and heterostructures^{20–23} and on the development of time-domain variants that lead to dramatic improvements in NMR resolution.^{9,24,25} Simultaneously, there has been a revival of interest in directly detected, optically pumped NMR (OPNMR).^{8,26–33} OPNMR measurements with direct detection have been used to investigate the properties of quantum confined conduction electrons in two-dimensional systems at low temperatures and high fields,^{34–38} a topic of considerable interest to condensed matter physicists.^{39–41} Notably, OPNMR measurements have provided the first evidence for and characterization of novel electron states called skyrmions in two-dimensional electron systems (2DES).^{34,35}

2 DIRECTLY DETECTED VS. OPTICALLY DETECTED

An important advantage of both time-domain and frequency-domain ODNMR methods is their extremely high sensitivity. Because of the high efficiency for detection of optical photons, it is possible in principle to detect the NMR spectrum of nuclei in the vicinity of single luminescent defect or impurity site in a semiconductor sample, comprising roughly 10⁵ nuclei. In fact, ODNMR spectra of single GaAs quantum dots containing approximately this number of nuclei have been reported,^{42–44} although in these experiments the NMR spectra were detected through modulation of the photoluminescence energy, rather than polarization, by manipulation of the optically pumped nuclear polarization. In ODNMR experiments in which photoluminescence polarization was monitored, NMR spectra of less than 10¹¹ nuclei have been detected.^{16,21}

An apparent limitation on ODNMR techniques based on photoluminescence polarization is that they can only be applied when the nuclear hyperfine field is a significant fraction of the external magnetic field. In practice, such ODNMR experiments are typically performed at magnetic field strengths below 1 T.

Advantageous features of directly detected OPNMR include: (1) compatibility with high fields (to the extent that the optical pumping effect itself occurs at high field);^{31,33} (2) absence of photoluminescence requirements; (3) ability to detect NMR spectra of both the ground state and the photoexcited state of the sample; (4) ability to detect NMR spectra of sample regions that are spatially distinct from the optically absorbing regions, through nuclear spin diffusion;^{34,35}

(5) full compatibility with pulsed NMR methodology, including multiple pulse line-narrowing techniques, heteronuclear decoupling, multidimensional spectroscopy, and nuclear spin relaxation measurements. Some of these advantages are shared by time-domain or time-sequenced ODNMR techniques.^{9,24,25} In principle, because optical pumping can produce nuclear spin polarizations of order 10%,^{8,9} the sensitivity of directly detected OPNMR is sufficient for the observation of roughly 10^{14} nuclei (with signal averaging), or the number of nuclei in a semiconductor monolayer with a surface area of approximately 0.2 cm^2 .

Examples of OPNMR spectra of bulk GaAs and InP are shown in Figures 1 and 2. Spectra of semiconductor quantum well samples are discussed in Section 4.

Very recently, all-optical NMR experiments on semiconductors, i.e., experiments in which nuclear spin transitions are

detected with only optical irradiation of a sample, have been reported.^{45–47} In these experiments, a near-infrared pump laser tuned near the semiconductor absorption band edge and propagating in a direction not parallel to the applied static magnetic field is pulsed^{45,46} or modulated in amplitude or phase⁴⁷ at radio frequencies, but no rf irradiation or pulses are applied. A plot of the Faraday rotation of a weaker probe laser^{45,46} or of photoluminescence polarization⁴⁷ versus the modulation frequency of the pump laser shows discontinuities at the NMR frequencies. Such experiments have been reported both for bulk GaAs^{45,46} and for GaAs quantum wells.^{46,47} Both single-quantum ($|\Delta m| = 1$) and overtone ($|\Delta m| = 2$) NMR transitions have been detected. Single-quantum transitions are attributed to modulation of electron-nucleus magnetic hyperfine couplings at the laser modulation frequency,^{45–47} while overtone transitions are attributed to modulation of nuclear electric quadrupole couplings at the laser modulation frequency.^{46,47} Observation of both types of NMR transitions is dependent upon optical pumping of nuclear spin polarizations away from resonance and subsequent destruction of the nuclear spin polarization at the resonant conditions. Further exploration and exploitation of all-optical NMR effects in semiconductors, and possibly other materials, is likely in the near future.

3 MECHANISM OF OPTICAL PUMPING

The general features of the physical mechanism of optical pumping in semiconductors have been described.⁷ Briefly, photoexcitation of a direct-gap, ZnS-structure, bulk semiconductor at the band edge (Γ point) in zero magnetic field creates conduction electrons with spin polarization $\langle S_z \rangle = \pm(1/4)\sigma$, where the light helicity σ is $+1$ for left-circular-polarized light, -1 for right-circular-polarized light, and 0 for unpolarized light. Provided that the spin-lattice relaxation time of photoexcited electrons is not much less than the photoexcitation lifetime, a net nonequilibrium electron spin polarization is created. The electrons couple to nuclei by Fermi contact hyperfine interactions. If the hyperfine interactions fluctuate with a sufficiently short correlation time, flip-flop transitions efficiently transfer electron spin polarization to the nuclei. At steady state, the nuclear spin temperature T_n is related to the electron spin temperature T_e and lattice temperature T by the expression $(T_n^{-1} - T^{-1}) = \gamma_e/\gamma_n(T^{-1} - T_e^{-1})$, where γ_e and γ_n are the electronic and nuclear magnetogyric ratios. Since $\gamma_e/\gamma_n \sim 10^3$, a small deviation of the electron spin polarization from thermal equilibrium produces a very low (positive or negative) nuclear spin temperature, i.e., a large nuclear spin polarization.

It is commonly assumed that optical pumping is driven primarily by localized electron states (e.g., electrons trapped at defect or shallow donor sites), rather than delocalized, Bloch-function states. This is because the rate of flip-flop transitions depends on the square of the hyperfine couplings, and therefore on the square of the electron probability density at the nuclei. Because the total electron probability density (not squared) is normalized, electron states that concentrate the probability density in a smaller volume can produce a greater net flip-flop rate.

Despite this general understanding of optical pumping, nearly all details of the mechanism remain mysterious. For example:

Figure 1 Optically pumped ^{71}Ga NMR spectra of a semi-insulating GaAs wafer at 4.3 K in a 9.39-T field, obtained with an optical pumping time of 10 s, a photon energy of 1.49 eV (831 nm wavelength), and the indicated light polarizations. The laser power was 240 mW in a 5-mm diameter spot. Emissive OPNMR signals are observed with linear and $\sigma+$ polarization. Under the conditions of these experiments, the optically pumped nuclear spin polarizations are of order 1%, but larger polarizations are created with longer pumping times. No NMR signals are detectable when the laser light is blocked, because of both the smaller nuclear spin polarization at equilibrium and the very long spin-lattice relaxation times in the dark ($>10^3$ s). Quadrupole splittings of the NMR lines arise from strain due to thermal contraction of the GaAs wafer, which was glued to a sapphire block in the low-temperature NMR probe

Figure 2 Optically pumped ^{31}P NMR spectra of a 348- μm thick Fe-doped semi-insulating InP wafer at 6 K, obtained in a superconducting magnet with a central field of 9.39 T. The InP wafer was located outside the homogeneous region of the magnet, producing a strong field gradient perpendicular to the surface of the wafer. The spectra then represent one-dimensional images of the nuclear spin polarization.⁸ (a) Low resolution images. The InP wafer is situated in a 0.195 T/cm gradient, with an optical pumping time of 600 s at 1.412 eV, or 878 nm wavelength. Spectra were obtained with $\sigma+$ and $\sigma-$ polarized light, at a power of 200 mW in a 3.7-mm diameter spot, and in the dark. The wafer thickness corresponds to an NMR frequency range of 116 kHz. With optical pumping, ^{31}P nuclei near the laser-irradiated surface acquire either positive or negative nonequilibrium spin polarizations, depending on the direction of light polarization. (b) High resolution images. The InP wafer is situated in a 0.453 T/cm gradient, with an optical pumping time of 120 s at the indicated photon energies. Spectra were obtained with $\sigma+$ polarized light, at a power of 25 mW in a 0.45-mm diameter spot. Vertical axis is reversed relative to (a). The absorption band edge for InP at low temperatures occurs at approximately 1.427 eV, where the light penetration depth is approximately 2 μm . As the laser is tuned to lower energies, the pumping light penetrates deeper into the wafer, producing an asymmetrically broadened ^{31}P NMR lineshape. A 2- μm distance corresponds to an NMR frequency shift of 1.6 kHz. (Adapted from Ref.⁸)

1. The identity of the localized states that produce optical pumping is not firmly established in any specific sample, either bulk or heterostructure.
2. The source of hyperfine fluctuations has not yet been identified conclusively. The classic Overhauser effect in a *metal* depends on hyperfine fluctuations due to translational motion of delocalized electrons near the Fermi surface. In optically pumped semiconductors, this contribution is considered negligible. Recent studies of the field dependence of optical pumping in GaAs and InP suggest that the relevant fluctuations have time scales of order 10 ps.^{31,33,48}
3. Possible effects of high fields on the band structure, optical selection rules, electron-hole pairing and localization, or other aspects of the photophysics relevant to optical pumping have not been explored in theory or experiment.
4. Possible contributions to the optical pumping process from hyperfine couplings to photoexcited valence band holes and effects of spin-selective electron-hole recombination⁴⁹ on the electron spin polarization have not been analyzed in detail.
5. The signs of optically pumped ^{31}P polarizations in undoped InP^{27,33} (but not Fe-doped, semi-insulating InP^{8,28}) have been found to be opposite to expectations based on the simple theory outlined above, i.e., $\sigma-$ and linearly polarized light produce negative ^{31}P polarization, while $\sigma+$ light produces positive polarization. In GaAs, the signs of optically pumped nuclear spin polarizations are in accord with expectations.
6. The dependences of nuclear spin polarization on the optical photon energy in bulk GaAs and InP are not well understood. In bulk GaAs, a strong maximum in the nuclear spin polarization is observed at photon energies approximately 20 meV below the band edge, and little or no polarization is created at higher energies.²⁹ This observation has been attributed tentatively to direct pumping of shallow traps or excitons.²⁹ In bulk InP, a similar maximum has been shown by stray-field NMR imaging to be due primarily to the increased optical absorption length (i.e., greater optically pumped volume) below the band edge.⁸ In bulk InP, substantial nuclear spin polarizations are generated with photon energies up to at least 60 meV above the band edge.^{8,27}
7. In GaAs/AlGaAs quantum well samples at high field, optical pumping effects saturate at very low photon flux,²⁶ of order 60 mW cm⁻², while photoluminescence does not saturate up to at least 3 W cm⁻². This observation suggests a ‘phase-space filling’ phenomenon in which a rather

low density of photoexcitations is sufficient to occupy all electronic states that play a role in optical pumping.

8. Recent OPNMR experiments on bulk InP have revealed that optical pumping creates nuclear spin dipolar order in addition to the Zeeman order predicted by the simple theory outlined above.²⁸ Possible explanations for optical pumping of dipolar order include direct generation through electron-nuclear cross relaxation, dependent on dipolar hyperfine interactions and nuclear dipole-dipole couplings,⁵⁰ and indirect generation through diffusion of Zeeman order in the presence of spatial gradients of NMR frequencies.²⁸ The dominant mechanism for optical pumping of dipolar order has not been established experimentally.

Obviously, there is a great deal of room for further research into the fundamental aspects of optical pumping in semiconductors. Nonetheless, even in the absence of a detailed understanding of the mechanism, the optical pumping effect can be useful both for sensitivity enhancement and for spatial localization of NMR signals. The utility of optical pumping is exemplified by OPNMR studies of 2DES in GaAs/AlGaAs quantum wells, as described below.

4 APPLICATION TO TWO-DIMENSIONAL ELECTRON SYSTEMS IN THE QUANTUM HALL REGIME

A 2DES, cooled to extremely low temperatures in a strong magnetic field, exhibits many exotic phenomena, including the integer⁵¹ and fractional⁵² quantum Hall effects that are the subject of a large body of experimental and theoretical studies by condensed matter physicists. Transport and optical studies of the 2DES have shown that the low-energy physics in these extreme conditions is driven by the electron-electron Coulomb interaction,⁵³ making this ‘simple’ system one of the hardest to understand theoretically. OPNMR studies have contributed to the recent progress on this problem by providing important new insights into the electron spin degree of freedom, which helps to shed light on the low-lying many-body states that exist in a real 2DES.^{39–41}

For these OPNMR experiments, samples typically contain multiple copies (up to forty) of a fundamental unit: a GaAs quantum well (i.e., a GaAs layer approximately 300 Å thick) doped with electrons ($n \sim 1 \times 10^{11} \text{ cm}^{-2}$), sandwiched between $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ barriers (i.e., $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ layers approximately 1500 Å thick).^{54–56} At low temperatures, all conduction electrons are confined to the quantum wells and are in the same ‘2D state’ (i.e., the lowest electronic subband of the well). The normal component of a strong magnetic field ($B \cos \theta$, where θ is the angle between the external field $\mathbf{B}$ and the direction normal to the plane of the quantum well) quantizes the 2D motion into spin-split Landau levels.^{54,55} In this regime, the many-body states and thus the physical properties of the 2DES are determined by the Landau level filling factor $\nu = (nhc/eB \cos \theta)$, where h , c , and e are Planck’s constant, the velocity of light, and the electron charge. By varying n , B , or θ , ν may be tuned to reach integral⁵¹ (e.g., $\nu = 1$) or fractional⁵² (e.g., $\nu = 1/3$) quantum Hall ground states.^{39–41,53} These are states in which the longitudinal resistivity ρ_{xx} of the 2DES vanishes and the transverse (or Hall) resistivity ρ_{xy} plateaus at the values $(hc/\nu e^2)$. In OPNMR experiments on

2DES in GaAs quantum wells,^{34–38,57,58} ν is varied for a sample with given n by varying θ and by performing experiments at several values of B .

Figure 3 shows ^{71}Ga OPNMR spectra of a multiple quantum well sample, acquired using the timing sequence SAT – τ_L – τ_D – DET.^{26,34,35,57} SAT represents an rf pulse train that saturates nuclear spin polarization. During τ_L , a near-infrared laser optically pumps the quantum well, using a photon energy above the band edge of the well and below that of the barrier. Because the laser is tuned to be absorbed only in the quantum well layers, only nuclear spins in the quantum wells, and not in the barrier, become strongly polarized. The enhanced NMR signal observed after a short illumination period (e.g., $\tau_L \sim 5 \text{ s}$) is due to nuclei in the quantum wells (‘W’ signals in Figure 3). Eventually (e.g., as $\tau_L \rightarrow 200 \text{ s}$), the optically pumped nuclear polarization spreads into the barrier regions

Figure 3 ^{71}Ga NMR lineshapes of an optically pumped GaAs multiple quantum well sample, obtained in a 12 T field at the indicated temperatures.³⁷ (a) Spectrum at Landau level filling factor $\nu = 1/3$ after approximately 60 s of optical pumping. Peak labeled W arises from nuclei in the 26-nm thick GaAs wells. Peak labeled B arises from the 312-nm thick $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ barriers between wells. The Knight shift K_S is defined empirically as the splitting between the peaks. The shaded lineshape is a simulation of the intrinsic Knight shift lineshape, with maximum shift $K_{S,\text{int}}$. The dashed line is a fit to the experimental lineshape obtained by convoluting the intrinsic lineshape with a Gaussian lineshape attributable to nuclear magnetic dipole-dipole couplings. (b) Temperature dependence of the optically pumped ^{71}Ga NMR lineshape at $\nu = 0.267$. (Reprinted from Ref.³⁷)

by nuclear spin diffusion. A second NMR signal due to nuclei in the barriers then appears ('B' signals in Figure 3). After a period τ_D in the dark ($\tau_D \geq 1$ s), nuclear free induction decay signals are recorded in the period DET. These signals probe the equilibrium properties of the 2DES as functions of ν and temperature. Nuclear spin-lattice relaxation rates R_1 at thermal equilibrium can be determined from the dependence of OPNMR signal amplitudes on τ_D^{35} .

The Knight shift (K_S) of quantum well signals may be defined^{26,34,35} as the peak-to-peak splitting between quantum well and barrier signals (see Figure 3). K_S is due to Fermi contact hyperfine couplings between nuclei and doped (not photoexcited, because the OPNMR signals are observed in the dark after τ_D) conduction electrons confined in the quantum wells and is proportional to the spin polarization of the 2DES. The temperature dependence of K_S [Figure 3(b)] reveals the increasing spin polarization of the electrons³⁶ as they are cooled into a ferromagnetic ground state⁵⁹ [see Figure 4(a)]. As shown in Figure 3(a) (dashed line), a more quantitative determination of K_S^{37} is achieved by fitting the experimental OPNMR lineshape to the convolution of the intrinsic hyperfine lineshape of the well and barrier [Figure 3(a), shaded] with a 3.5 kHz FWHM Gaussian lineshape due to nuclear magnetic dipole-dipole couplings. The central assumption of this model of the lineshape is that nuclei in the quantum well experience a hyperfine magnetic field that scales with the electron probability density in the direction perpendicular to the plane of the well but is uniform in the plane of the well. This model requires that any reversed electron spins [e.g., thermally excited spin waves, see Figure 4(b)] are delocalized within the plane of the quantum well, such that the electron spin polarization appears spatially homogeneous when averaged over the time scale of the NMR experiment, which is of order 40 μ s. Simulated OPNMR lineshapes in this motionally-narrowed limit fit the experimental spectra at $\nu = 1/3$ and $\nu = 1$ over the observed temperature range.

The experimentally determined $K_S(T, \nu)$ represents a direct and calibrated measure^{34,36} of the 2DES spin polarization $P(T, \nu) \equiv \langle S_z(T, \nu) \rangle / \max(S_z)$. Figure 5 shows $P(T, \nu)$ measured by OPNMR at three important filling factors, $\nu = 1$,⁶⁰ $\nu = 1/3$,³⁶ and $\nu = 1/2$.³⁸ Both the $\nu = 1$ and the $\nu = 1/3$ electronic states become fully polarized in the low temperature limit [see Figure 4(a)], in agreement with theoretical predictions^{59,61–63} that these integer and fractional ground states are quantum Hall ferromagnets (QHFM). $P(T, \nu)$ decreases with increasing temperature due to thermally excited spin-waves [see Figure 4(b)]. Data at $\nu = 1$ were obtained at $B \approx 7$ T, where the electron Zeeman energy corresponds to a temperature $T_Z \approx 2.1$ K, whereas data at $\nu = 1/3$ were obtained at $B \approx 12$ T, where $T_Z \approx 3.5$ K. The more rapid drop-off of $P(T, \nu = 1/3)$ shows the dominant role that the electron-electron Coulomb interaction plays in the spectrum of excited states.⁶¹ Specifically, the 'spin stiffness' at $\nu = 1$ is expected⁶⁴ to be much higher than at $\nu = 1/3$, which means that the number of spin waves present at low temperature is much less for $\nu = 1$, consistent with the data (Figure 5). OPNMR measurements of $P(T, \nu = 1)$ have stimulated additional progress on the theoretical description of QHFM,^{65–68} since the conventional assumption of dilute spin waves can not describe the experiments once the temperature exceeds T_Z .

Figure 5 also shows OPNMR measurements of $P(T, \nu = 1/2)$, which appear to indicate a partially polarized 2DES

Figure 4 Illustration of electronic states in a two-dimensional system at low temperatures and high magnetic fields, as for conduction electrons in a OPNMR experiments on GaAs quantum wells. (a) At very low temperatures and Landau level filling factor $\nu = 1$, the electrons fill the lowest state of translational energy with maximum spin polarization, producing the maximum Knight shift in an OPNMR measurement. (b) At somewhat higher temperatures, thermally excited electron spin waves reduce the electron spin polarization, thereby reducing the Knight shift. (c) At very low temperatures and filling factors slightly above one, additional electrons must occupy spin-reversed states. Electron-electron interaction energies are minimized by tilting the spins of neighboring electrons, resulting in a more rapid destruction of the electron spin polarization and Knight shift than expected in the non-interacting limit. The electronic ground state contains skyrmions

state in the low-temperature limit.³⁸ These data also drop off more rapidly with increasing temperature than data taken in either the integral ($\nu = 1$) or the fractional ($\nu = 1/3$) quantum Hall regimes. Both observations are qualitatively consistent with the emerging picture that the $\nu = 1/2$ state is best described as a compressible (i.e., gapless) state of composite fermions.^{69–77} OPNMR measurements of $P(T, \nu = 1/2)$ and of the temperature dependence of the nuclear spin-lattice relaxation rate $R_1(T, \nu = 1/2)$ provide important constraints^{38,78} on the theoretical description of the $\nu = 1/2$ state and shed new light on the nature of the composite fermion.^{79,80}

Figure 5 Temperature dependence of the electron spin polarization of a GaAs quantum well at integral ($\nu = 1$) and fractional ($\nu = 1/2$, $\nu = 1/3$) filling factors, determined from Knight shifts in OPNMR spectra. Two-dimensional electron systems at $\nu = 1$ and $\nu = 1/3$ exhibit the integer and fractional quantum Hall effects, respectively. The electronic ground state at $\nu = 1/2$ is described theoretically as a compressible (i.e., gapless) state of composite fermions

Figure 6 Dependence of the ^{71}Ga Knight shift on filling factor (open circles), obtained from OPNMR measurements on a multiple quantum well sample with 30-nm thick GaAs wells and 180-nm thick $\text{Al}_{0.1}\text{Ga}_{0.9}\text{As}$ barriers at a field of 7.05 T and 1.55 K. The filling factor was varied by tilting the sample in the field. The solid line is the theoretical curve for noninteracting electrons in a two-dimensional system. The dashed lines are fits to the data, assuming a skyrmion model in which each skyrmion carries an effective spin of 1.8, or 3.6 times the spin of a single electron. Data of this type provided the first experimental evidence for skyrmions in two-dimensional electron systems. (Reprinted from Ref.³⁴)

OPNMR data on GaAs quantum wells, such as the data in Figure 6, also provided the initial experimental evidence^{34,35} for novel charged spin-texture excitations^{62,63} called skyrmions in 2DES. To understand the meaning of a skyrmion state, consider the ground state of the QHFM at $\nu = 1$ (Figure 4(a)), and then add one electron (at fixed temperature), to move

to $\nu = 1 + \epsilon$. By the Pauli exclusion principle, the spin of the additional electron must be reversed with respect to the electron spins at $\nu = 1$. However, theory predicts a more dramatic effect: to minimize electrostatic repulsions, nearby electron spins will twist as well, making nearest neighbors more nearly parallel, until the reduction in Coulomb energy is balanced by the higher Zeeman energy of multiple reversed electron spins.⁵⁹ The resulting many-body state, a skyrmion, has one more electron but many more net reversed spins (~ 3 per additional electron in most experiments), relative to the $\nu = 1$ ground state. As shown in Figure 6, $K_s(\nu)$ at low temperature, and thus $P(\nu)$, drops rapidly³⁴ as more skyrmions (or antiskyrmions, corresponding to $\nu = 1 - \epsilon$) are added to the system^{63,81} by moving farther above or below $\nu = 1$. A similar drop has been reported⁸² near $\nu = 3$. The presence of many skyrmions also leads to a strong dependence of R_1 on ν near the integral quantum Hall condition.³⁵ From a purely phenomenological standpoint, the effects of varying ν can be quite dramatic: at 2.1 K and 7.05 T, the spin-lattice relaxation rate of ^{71}Ga nuclei in a GaAs quantum well near $\nu = 1$ changes by a factor of 20 when the sample is rotated by only 3° ! Similar effects have subsequently been observed in specific heat measurements.^{83,84}

As Figure 4(c) shows, the size of the skyrmion is expected to be much less than that of spin waves [which are extended objects, Figure 4(b)], but also much greater than the inter-nuclear spacing of roughly $3 \text{ \AA}$. The spatial extent of the skyrmion is relatively unimportant at temperatures where skyrmions are delocalized and the OPNMR spectra are motionally narrowed³⁷ (i.e., the time-averaged value of $P(T, \nu)$ is invariant to translation in the plane of the quantum well).

Figure 7 Dependences of the Knight shift (filled symbols) and quantum well NMR linewidth (open circles) on temperature, from ^{71}Ga OPNMR measurements on GaAs quantum wells at filling factors $\nu = 1.00$ (triangles), 0.969 (diamonds), 1.045 (squares), and 0.949 (circles). Lines are guides to the eye. The non-monotonic temperature dependence of the linewidth indicates a transition from the motionally narrowed limit at higher temperatures towards the static limit at lower temperatures, where the motion in question is translation of skyrmions in the plane of the quantum well

However, for $\nu \neq 1$, Figure 7 shows that lowering the temperature causes the width of the quantum well lineshape (open symbols) first to increase and then to decrease,⁸⁵ in stark contrast with the temperature independence of the quantum well linewidth at $\nu = 1$. Similar trends were uncovered in earlier measurements³⁷ near $\nu = 1/3$. The non-monotonic temperature dependence of the linewidth in Figure 7 is consistent with the evolution of the quantum well OPNMR lineshape from the motionally narrowed regime to the static regime as the temperature is lowered. Specifically, the motion at higher temperatures is that of delocalized skyrmions. As the temperature is lowered, fluctuations in local hyperfine fields freeze out as the skyrmions become localized. With spectra approaching the frozen limit, future OPNMR measurements should provide new details about the spatial distribution of skyrmions in a 2DES and the nature of the many-skyrmion ground state, which may possess unusual order.^{86–92}

5 CONCLUDING REMARKS

More than three decades have passed since the first demonstration by Lampel⁶ of optical pumping of nuclear spins in a semiconductor and of directly detected, optically pumped NMR. As described in this chapter, Lampel's early work has been followed by a large number of interesting methodological extensions, including the development of ODNMR techniques, time-domain ODNMR, and high-field OPNMR, and important applications, most notably the use of OPNMR as a probe of the properties of conduction electrons in two-dimensional systems in the quantum Hall regime of low temperatures and high magnetic fields. Because of the practical importance of sensitivity enhancement in all areas of NMR and the commercial and scientific importance of semiconductor devices, investigations and applications of optical pumping effects in semiconductors are certain to continue. Likely areas for future research include clarifications of the physical mechanism of optical pumping in semiconductors, investigations of optical pumping effects in other semiconductor materials and other quantum-confined structures (e.g., quantum dots), further development of all-optical NMR methods, and possibly the use of optically pumped semiconductor wafers as sources of nuclear spin polarization for sensitivity enhancement in NMR measurements on organic or biological materials deposited on the semiconductor surface.²⁷

Biographical Sketches

Robert Tycko, b 1959. A.B., 1980, Princeton University. Ph.D., 1984, University of California at Berkeley. Began his career at AT&T Bell Laboratories, where he developed new solid state NMR methods, such as zero-field NMR in high field, and applied solid state NMR to problems in condensed matter physics. Moved to the National Institutes of Health in 1994, and now develops and applies solid state NMR methods for structural studies of biopolymers. Approx. 100 papers on all areas of magnetic resonance. Research interests: optical pumping, NMR theory and methodology, structure of proteins and amyloid fibrils.

Sean E. Barrett, b 1965. A.B., 1987, Princeton University. Ph.D., 1992, University of Illinois at Urbana-Champaign. Recipient of the 1995 William L. McMillan Award for outstanding contributions to condensed matter physics, in particular the development at AT&T Bell Laboratories of optically pumped NMR as a probe of two-dimensional electron systems. Approx. 25 papers on NMR in condensed matter physics. Research interests: optical pumping, two-dimensional electron systems, high-temperature superconductivity.

Quantum Tunneling Spectroscopy

1 INTRODUCTION

Low-temperature molecular tunneling spectroscopy is of interest for four reasons: it continues into the quantum domain the study of molecular motion, it provides an outstanding example of a classical to quantum transition, it extends NMR and spin thermodynamics into the adjacent domain of coherent molecular dynamics, and finally it clarifies historical conceptual problems concerning particle indistinguishability and the topology of rotation space. The main results have recently been surveyed.¹

The rotations of hindered symmetrical groups like CH₃ and NH₄ in solids persist to helium temperatures where the motion of hindered triangular rotors like CH₃ is characterized by a discrete frequency, the tunnel frequency ω_t , derived from the overlap of ground state librational oscillator wavefunctions localized in adjacent wells of a three-well potential. A typical low-temperature CH₃ spectrum consists of three frequencies: $\pm\omega_t$ and 0. The quantum motion of tetrahedral rotors like NH₄ and ND₄ is more complicated,² with several tunnel frequencies associated with rotation about the different symmetry axes. The structured spectrum changes with increasing temperature towards a Lorentzian peak with a halfwidth $1/\tau_c$, where τ_c is an orientational correlation time. This spectrum is explained by a quasi-classical hopping model. The transition, which has been studied by both magnetic resonance and neutron scattering,³ is illustrated in Figure 1.

2 THE ROTATIONAL SPECTRUM OF A TRIANGULAR ROTOR

2.1 Stationary States

Low-temperature states have well-defined wavenumbers k . The change from well-defined orientation at high temperatures is similar to the change from hopping conduction to band conduction of polarons and excitons. Like these phenomena, molecular rotation is modeled by a particle in a periodic potential with an orientation coordinate ϕ and a hindering potential $V \cos 3\phi$. Special features are due to the finite extent,

Figure 1 The rotational spectrum of a hindered CH₃ group changes from three frequencies $\pm\omega_t$ and 0 at low temperature to a Lorentzian spectrum of rotational hopping motion at high temperature. The figure is a model with a single temperature-dependent parameter that gives a good representation of observations in many materials. The temperature and frequency scales depend on the height of the hindering barrier

2π , of the rotational coordinate space. For stationary states, we assume a cyclic boundary condition $\psi(\phi + 2\pi) = \psi(\phi)$ and the Hamiltonian

$$\hat{\mathcal{H}} = -\frac{\hbar^2}{2I} \frac{\partial^2}{\partial \phi^2} - V \cos 3\phi \quad (1)$$

whose eigenvalues for the lowest band are

$$\hbar\omega(k) = -\frac{2}{3}\hbar\omega_t \cos \frac{2}{3}\pi k \quad (2)$$

The eigenfunctions are Bloch waves with k lying between $\frac{3}{2}$ and $-\frac{3}{2}$. The boundary condition selects $k = \pm 1$ or 0. The energies are thus $-\frac{2}{3}\hbar\omega_t$ and $\frac{1}{3}\hbar\omega_t$, the latter being doubly degenerate. The three frequencies derived from the energy differences are $\pm\omega_t$ and 0, the low-temperature spectrum.

2.2 Excitations and Dynamics

When dynamical interaction with the environment is included, the space ϕ is open and may be envisaged as a helix upon which wavepackets rotate.⁴ A wavepacket confined to one turn of the helix is single-valued within a range 2π and is formed by superposing two of the eigenfunctions of equation (1). Two nodes separated by 2π form the leading and trailing edges of the wavepacket. Three elemental wavepackets rotate with the angular velocities $\pm\omega_t$ and 0. Generation of wavepackets from the stationary states and their subsequent evolution in time can be compared with a 90° pulse and subsequent free induction decay in NMR. The rotation is observable, because it modulates spin-dependent interactions so that molecular rotation and NMR are intimately linked. Thermal excitation results in a transfer of angular momentum, which changes the average wavenumber, $k_a = \pm\frac{1}{2}$ or 0 to

$k_a + \sigma$, $\hbar d\sigma/dt$ being the torque. The general rotation frequency derived from equation (2) is

$$\omega_{k_a, \sigma} = (\frac{3}{4})^{-1/2} \omega_t \sin[\frac{2}{3}\pi(\sigma + k_a)] \quad (3)$$

A distribution of σ explains the broad rotational spectra of Figure 1. Relaxation to stationary states with integer k causes σ to approach zero as the temperature falls.

A wavepacket only has large amplitudes in the potential wells, and can be represented by three complex amplitudes. The three elementary wavepackets can be superposed by adding their amplitudes to form a more general wavepacket whose evolution involves all three frequencies $\omega_{k_a, \sigma}$. This complex wavepacket rotates and oscillates in shape. At low temperature, the frequency 0 is the rotation frequency and the frequencies $\pm\omega_t$ are shape oscillations. Thus the rotor comes to orientational rest, but continues its internal oscillations. This character changes smoothly into one of rotation as σ grows in absolute value. When $\sigma = \frac{3}{4}$, the complex wavepacket rotates clockwise, moving smoothly through each of the three wells in turn. To accomplish the passage between wells, the shape of the wavepacket oscillates in sympathy with the rotation. The coherent evolution of wavepackets for $\sigma = 0$ and $\sigma = \frac{3}{4}$ is compared in Figure 2.

2.3 Combined Spin and Rotational Dynamics

As an alternative to a reference frame in which the lattice is stationary, it is useful to use a frame in which the wavepacket

Figure 2 A methyl group wavepacket is described by three intensities in three potential wells on a circle. At low temperature (a), the wavepacket oscillates in shape without rotating. A rotational impulse changes the motion to one of coherent rotation (b), the correlated shape oscillations now assisting the passage from well to well

is stationary. In this frame, σ appears as a vector potential in the angular momentum operator and the wavenumbers remain integers. Observables are the same whichever frame is used. The vector potential can be incorporated into a spin Hamiltonian to combine quantum rotation and spin dynamics. In the case of a methyl group,

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{DD} + \hat{\mathcal{H}}_R \quad (4)$$

$$\hat{\mathcal{H}}_R = -\frac{1}{3}\hbar\omega_t(\hat{R}e^{i2\pi\sigma/3} + \hat{R}^{-1}e^{-i2\pi\sigma/3}) \quad (5)$$

where $\hat{\mathcal{H}}_Z$, $\hat{\mathcal{H}}_{DD}$, and $\hat{\mathcal{H}}_R$ are the Zeeman, dipole–dipole, and rotation Hamiltonians. The basis functions are the eight product spin states of three protons at the three lattice sites. These states can be regarded as shorthand for Slater determinants. The operator $\hat{R}$ cyclically permutes the three spin states round the lattice sites. Rotation clockwise through $\frac{2}{3}\pi$ introduces the phase change $\frac{2}{3}\pi\sigma$ and rotation anticlockwise the reverse phase change. Changes in σ arise owing to collisions between one of the methyl protons and a neighboring atom. This formalism can be extended to tetrahedral molecules.

A spin state is propagated by equation (4). The new feature compared with ordinary spin dynamics is inertia. Whereas the precession frequency of a spin depends only on the instantaneous magnetic field, the rotation frequency of a methyl group depends on the previous dynamical history. The evolution involves two coupled equations: the time-dependent Schrödinger equation and the differential equation for σ . For thermal excitations, some stochastic assumption concerning $d\sigma/dt$ must be made. Another torque is due to the angular dependence of the dipole–dipole energy. This can be obtained by rotating the state slightly using $\lambda\hat{R}$, where λ is small, and finding the rate of change of dipolar energy. The change in the dipole–dipole energy due to rotation, familiar at high temperatures, has a low-temperature counterpart in which molecular rotation changes owing to the angular dependence of the dipole–dipole energy.

2.4 The Quantum-to-Classical Transition

The temperature dependence of the rotational spectrum is remarkably similar for all materials except for the scaling of temperature with barrier height. The host lattice serves as a heat bath, destroying coherence and exerting a fluctuating torque. The notable feature is that the outer (shape oscillation) peaks of the low-temperature rotational spectrum move inward with increasing temperature. There have been many theories of this,³ which can be divided (see Section 3) into those that attribute the reduction to properties of the host lattice and those that regard it as an essential feature of the quantum-to-classical transition. The latter view is that the wavepacket shape oscillations slow down to meet the rising rotation rate in order to play their new role of assisting rotation, while fluctuations in the rotation rate broaden the spectrum. The simplest idea⁴ is that the slowing can be described as a spectral averaging process. Orientational hopping is assumed to be accompanied by hopping in k -space. In this way, increasing localization in space is compensated by delocalization in k -space. The frequencies of the low-temperature spectrum are assumed to hop between $\pm\omega_t$ and 0 owing to k modulation,

while each is also subject to random phase modulation due to the changes in orientation. The spectrum is obtained by summing the elements of a matrix $\mathbf{M}^{-1}$, where

$$\mathbf{M} = \begin{bmatrix} i(\omega_l - \omega) - 2\rho - \delta & \rho & \rho \\ \rho & i(-\omega_l - \omega) - 2\rho - \delta & \rho \\ \rho & \rho & -i\omega - 2\rho - \delta \end{bmatrix} \quad (6)$$

Here ρ represents the rate of k hopping and δ the rate of orientational hopping. Both are identified with $1/\tau_c$. At low temperatures, $1/\tau_c \ll \omega_l$, and the frequencies and halfwidths $3/\tau_c$ of the three peaks are obtained from the diagonal elements of equation (6). At high temperatures, ω_l may be neglected. The spectrum is centered at $\omega = 0$, and the halfwidth is $1/\tau_c$. The classical hopping model is thus extended to the quantum regime. Figure 1 is calculated in this way. The parameter $1/\tau_c$ typically obeys an Arrhenius law, and can be roughly equated with a thermal average of the bandwidths of occupied excited librational states. The temperature dependence of the rotational spectrum is thus obtainable from the tunneling frequency without adjustable parameters.

3 FUNDAMENTAL CONSIDERATIONS

3.1 Indistinguishability

Particle indistinguishability has a crucial role in the theory. According to an argument from early quantum theory,⁵ the hindering potential for symmetric molecules must be invariant to the interchange of the space and spin coordinates of the protons. For a methyl group, this means a threefold symmetry,⁶ which prevents excitation of wavepackets and is inconsistent with the high-temperature hopping model. Though the symmetry constraint correctly identifies the stationary states of a hindered methyl group by excluding nonintegral k , it is incompatible with wavepacket dynamics. The reason is that wavepackets and stationary states have different topologies. Consider the evolution from one to the other. A superposition of two similar wavepackets $\psi(\omega t)$ and $\psi(\omega t - \gamma) \exp(\frac{1}{2}i\gamma)$ is a stationary state if $\gamma = (2n + 1)\pi$. As a stationary state is approached, the helical space-time path of the wavepacket broadens, and turns of the helix overlap. The number n of rotations in a time $2\pi/\omega$ becomes ambiguous. Destructive interference between paths of different n restricts k to integral values. When the coordinate ωt disappears, the labels that in wavepacket states refer to nonidentical proton trajectories refer to identical indistinguishable particles. The symmetry constraints with antisymmetrization ensure that the phase is continuous and the Pauli principle is satisfied. Excitations restore the helical space-time topology and the proton trajectories. The constraints no longer strictly apply, but quantum behavior results while wavepackets imperfectly reflect the topology of neighboring stationary states.

3.2 The Topology of Rotation Space

The identification of labels with particles also leads to the identification of molecular rotation with the symmetry operation of permutation. This is only possible if the rotation

space ϕ is closed. Symmetry-constrained theories consequently allow only integral wavenumbers and limit dynamics to transitions that conserve the wavenumber. This makes them completely different from other transport theories, and gives rise to the view that rotation is fundamentally different from translation. The unconstrained theory of Section 2 has affinities with superconductivity, SQUIDs and quantum transport phenomena in general, besides linking with the hopping model of transport.

4 EXPERIMENTS AND TECHNIQUES

The first effect of tunneling rotation to be observed was that motionally narrowed NMR lines of methyl-containing compounds often fail to broaden when the temperature is reduced to 4 K. With falling temperature, the frequency of components of the dipole-dipole interaction converge on $\pm\omega_l$, as in Figure 1, giving rise to discrete sidebands of the NMR spectrum. The total second moment of the NMR spectrum is conserved, so the sidebands are very weak if the tunnel frequency is large. The failure to broaden demonstrates that $\omega_l/2\pi$ exceeds a few tens of kilohertz. ESR studies of free radicals containing rotating methyl groups in the fragment C-CH₃ display more detail. At high temperature, the hyperfine spectrum is a 1 : 3 : 3 : 1 quartet, indicating equal interaction of the electron spin with the three protons. When the temperature is reduced, the spectrum changes to a seven-line pattern 1 : 1 : 1 : 2 : 1 : 1 : 1 with half the spacing of the quartet, the two inner peaks of the quartet having split into 1 : 1 : 1 triplets.⁶ The splitting is due to two of the three methyl states with magnetic quantum number $\frac{1}{2}$ forming stationary wavepackets—one in the orientation that minimizes the hyperfine energy and one in the orientation that maximizes it. The energy difference is the separation of the outer members of the triplet. The central member of the triplet has $k = 0$. The collapse of the outer members of each triplet on to the central member is due to the two wavepackets hopping between the two orientations and averaging the orientationally dependent energy. As the rate of rotation increases, the tunnel frequency falls to join it, as in Figure 1. The effect is that all three members of the triplet are involved in the motional averaging process. This is observed through the fact that the central member of the triplet does not remain narrow, while the outer pair merges with it.

The main ESR transitions correspond to flips of the electron spin, while the nuclear quantum number m remains unchanged. Transitions in which m also changes give rise to weak sideband transitions, which enable the tunnel frequency to be measured with precision. The detection of such transitions, their approximate location having been previously deduced by ENDOR, marked the true beginning of tunneling spectroscopy, the motional spectrum being clearly separate from the pure magnetic transitions. Similar tunneling sidebands of NMR spectra open a frequency window in the region of 200 kHz, rather than the 100 MHz range of ESR. Level crossing or tunnel resonance techniques⁷ greatly aid the detection of weak sideband transitions and extend the range of accessible tunnel frequencies. A magnetic field is chosen such that the molecular tunnel frequency is equal to a Larmor frequency—either the electron Larmor frequency for free radicals or the nuclear Larmor frequency in ordinary materials. At these internal resonances, transfer of energy between magnetic and rotational

energy occurs through a resonant relaxation process. Energy is exchanged between a Zeeman reservoir and a tunneling reservoir, each of which relaxes to the lattice by its own relaxation process. The ideas of spin thermodynamics are extended, and the process provides an extremely sensitive way of detecting tunnel frequencies. It requires the ability to vary the magnetic field. This is done either by changing the NMR measurement frequency or by using field cycling. There are two versions of the technique. In one, the sample is doped with paramagnetic impurities, often by γ irradiation, and the tunnel frequency is tuned to the electron Larmor frequency. In the other, the tunnel frequency is tuned to the nuclear Larmor frequency. Together, these cover the range from a few megahertz to 50 GHz. With paramagnetic impurities, what is observed is a dynamic polarization effect at the magnetic field of the internal resonance. Energy is transferred between the electron Zeeman and tunneling reservoirs when there is a small mismatch in their frequencies, the energy balance being made up by the nuclear Zeeman system, which is heated or cooled according to the sign of the mismatch.

The direct observation of tunneling sideband transitions is generally difficult, because they must be driven with a field that is nonuniform across the molecule. It is the dipole–dipole interaction, mixed into the magnetic states, that drives the transitions. This effect is naturally stronger at low fields. Low-field dipole–dipole driven NMR has consequently proved to be a powerful way of studying tunneling. Either a true low field⁸ using field cycling or a low effective field in the rotating frame⁹ may be employed, and both have given good results. They cover the frequency range from 60 kHz to 1 MHz, and thus link with tunnel resonance methods to provide a spectroscopy covering six decades of frequency. An example of a low-field spectrum is shown in Figure 3. Double resonance techniques can be employed to increase population differences and enhance transitions. The next frontier to still lower frequencies has recently been breached by the use of the Lee–Golburg method of line narrowing. Low-field Fourier transform tunnel spectroscopy is conducted slightly off-resonance in the rotating frame.¹⁰ Another recent development in low-field spectroscopy is the use of SQUID detection.¹¹ It seems likely that developments in the future will come from the increasing exploitation of NMR time domain

Figure 3 The low-field dipole–dipole driven NMR spectrum of dimethylmalonic acid obtained at 4.2 K. The proton Larmor frequency is 210 kHz and the tunnel frequency that splits $m = \frac{1}{2}$ and $-\frac{1}{2}$ levels is 330 kHz

techniques to interchange magnetic and rotational order, using the spins to monitor the coherent tunneling motion.

There are many other phenomena associated with tunneling rotation that a brief review cannot cover, but two observations connected with nearly free rotors should be mentioned. The Haupt effect¹² is a spectacular nuclear dynamic polarization effect that occurs when the temperature of 4-methylpyridine is changed at fairly low temperatures as the slow evolution in the rotational states of the nearly free methyl group drives a large change in the dipole–dipole temperature. The second effect¹³ is the optical observation of fractional quantization of the rotation of nonequilateral triangles of nitrogen atoms in molecular beams. Molecular quantum rotation covers a very wide range of phenomena. Because of its dynamical simplicity, it very clearly exhibits features that are common to all quantum systems.

1 INTRODUCTION

Problems of collective ordering have fascinated scientists as well as laymen for many years, and have brought a growing, interdisciplinary community together where mathematicians, physicists, chemists, meteorologists, biologists, engineers, and sociologists—to name but a few—try to reach a common understanding of the dynamics of complex physical or mathematical nonlinear systems. A new branch of scientific life has thus evolved, which has been named ‘synergetics’ by its founder, Hermann Haken.¹ Its subjects are many body systems with nonlinear interactions among the individuals—‘social systems’ so to speak—which are in contact with their surroundings (reservoirs of heat, mass, food, or information), and further with pumping devices, feedback systems, forcing fields, modulators, control devices, and so on.

An outgrowth of synergetics has been the discovery that the nonlinear response of a self-ordered many body system can often be drastically reduced to that of a low-dimensional system by Haken’s slaving principle. There, only a few relevant macroscopic variables, the order parameters, play the role of masters. A typical representative thereof is the laser, with its large number of radiating entities and field quanta. However, owing to cooperative interactions, most degrees of freedom are frozen in—only a few survive slaving and determine the laser activity. This then allows a quantitative comparison of experimental observations with low-dimensional differential models in an appropriate phase space.²

A laser consists typically of two main components: the radiating particles (atoms, molecules, electrons, nuclei, etc.) and the radiation field produced by them. An external pump causes population inversion, where the higher energy states are more strongly populated than the lower ones. A resonant structure (cavity), which encloses the particles, provides feedback for the radiation field, thus causing above laser threshold coherent excitation and radiation of the particles.

In the ruby NMR laser (Figure 1), the lasing ‘particles’ are the nuclear spins of the ^{27}Al in $\text{Al}_2\text{O}_3:\text{Cr}^{3+}$, and the radiation field is a magnetic radiofrequency field sustained by the tuned NMR coil that forms the cavity of the laser. Spin inversion beyond the first laser threshold is obtained by means of dynamic nuclear polarization (DNP) at the ruby lattice

temperature of 4.2 K. DNP is achieved by shining microwaves at Cr^{3+} , thus causing electronic transitions that pump the nuclear spins to the lasing state. The NMR cavity is normally tuned to ν_a . The NMR laser thus acts as a tuned, single mode, homogeneously broadened, unidirectional laser. The NMR laser field induces a voltage in the receiver coil L , which can be tapped at the tuning capacitor C_T . The NMR laser signal thus is a voltage $V(t)$ across C_T that oscillates at ν_a . Since the laser dynamics involves primarily regular variations of the amplitude of V , the rf laser signal is demodulated, and its envelope $v(t)$ only is recorded. We call $v(t)$ the laser output.

The ruby NMR laser, a solid state nuclear spin flip laser, operates typically at the central NMR frequency $\nu_a = 12.3 \text{ MHz}$ of ^{27}Al in a static magnetic field $B_0 = 1.1 \text{ T}$. Therefore it may also be called a RASER, since it is a generator of coherent radiowaves rather than light, but having many of the virtues of a generic laser.

Ever since the discovery of radio wave amplification by stimulated emission of radiation in ruby ($\text{Al}_2\text{O}_3:\text{Cr}^{3+}$) by Bösigger,³ we have been intrigued by the question of how to describe quantitatively the physics of the collective ordering of the ^{27}Al nuclear spins in that solid. In particular, with the discovery of laser chaos (see *Laser Devices in NMR: Routes to Chaos*), the central problem in investigations of chaotic behavior has been to construct realistic models and relate them to a wide as possible spectrum of observations from different modes of operation. A general theory that treats the ruby NMR laser has not yet been formulated, and we still have to limit ourselves to grossly simplified models. They are derived from the famous Bloch equations and Kirchhoff rules, which describe classically the collective dynamics of the ^{27}Al spins and the electronic circuitry that provides the laser field.⁴ Nuclear spin relaxation is introduced phenomenologically by the use of relaxation times or relaxation rates; DNP is expressed by a pumping rate and a pumping level. These quantities enter the model as system parameters that reflect in an average sense the exceedingly complicated interactions among the nuclear and electronic spins and their coupling to

Figure 1 The basic components of the NMR laser. The anti-Helmholtz coils are used for linewidth modulation. In the case of Q modulation, the resistance of a pin diode in parallel to C_T is varied sinusoidally

the crystal electric field and to the external microwave field that ultimately pumps the ^{27}Al . Spin–spin interactions mediate the energy transfer from the lasing spins to the pumping field as well as to the lattice. Spin–spin interactions are also responsible for the irreversible dephasing of the radiating ^{27}Al nuclei.

2 SPIN DYNAMICAL ASPECTS OF RUBY

The performance of the ruby NMR laser depends strongly on the coupling of the nuclear ^{27}Al and electronic Cr^{3+} spins with magnetic and electric fields and among themselves.⁵ The Hamiltonian of the combined nuclear and electronic spin system can be separated into terms that reflect magnetic (Zeeman), electric (crystal field), and spin–spin (dipole–dipole) interactions. There appear mutually commuting and noncommuting terms, $\hat{H}_i$ and $\hat{H}_{ik}$, respectively. Each of the commuting operators characterizes an energy reservoir of many degrees of freedom. Since the crystal field effects are small compared with the Zeeman interaction, we speak somewhat loosely of the nuclear and electronic Zeeman reservoirs, which are coupled to dipole–dipole interaction reservoirs. In thermal equilibrium, a spin temperature θ_i may be assigned to each of these subsystems.

The noncommuting operators describe internal couplings (spin–spin and spin–lattice) or interactions with time-dependent external fields, and are treated as perturbations. They are responsible for the energy flow between the reservoirs. The internal couplings tend to equalize the temperatures with time constants τ_{ik} (dephasing or relaxation and cross-relaxation times): they reflect dissipation. In contrast, the interactions with coherent radiation fields tend to offset the overall thermal equilibrium: they may produce spin order—for example, by pumping of spin states or phasing of otherwise randomly oriented single spins.

2.1 Bulk ^{27}Al and Impurity Cr^{3+}

The lasing ‘particles’ in ruby are the magnetic dipole moments of the 100% abundant ^{27}Al nuclei, which interact with the static magnetic field $\mathbf{B}_0$ and the radiation field $\mathbf{B}(t)$ by the magnetic dipole interaction. ^{27}Al has spin- $\frac{5}{2}$, the gyromagnetic ratio $g = 6.97 \times 10^7 \text{ s}^{-1} \text{ T}^{-1}$ (we use the symbol g instead of γ , which is reserved for relaxation rates; in so doing, we follow the notation of quantum optics), and an electric quadrupole moment. In ruby, ^{27}Al occupies equivalent sites. The nuclear Zeeman levels $E_m = -mghB_0$ ($m = \pm\frac{5}{2}, \pm\frac{3}{2}, \pm\frac{1}{2}$) are thus uniquely shifted by the quadrupolar interaction of ^{27}Al with the crystal electric field. This amounts to five, in general different, resonance frequencies $\omega_a^{(i)}$ for the $\Delta m = \pm 1$ spin flip transitions. Since the LC circuit that forms the laser cavity has only one resonance frequency, $\omega_c = 1/\sqrt{LC}$, the NMR laser has at most five modes. However, single mode NMR laser activity is possible when the coil is tuned to a selected NMR transition. In this case, the spin inversion should not exceed a value at which multimode excitation occurs. Unless stated otherwise, we restrict ourselves to the single mode activity of the strongest ($\frac{1}{2}, -\frac{1}{2}$) NMR transition of frequency $\omega_a = gB_0$: the central NMR mode.

Figure 2 FID below laser threshold. Note the exponential decay and its slowing down due to the radiative feedback of the inverted spin system in the NMR coil

The Cr^{3+} impurity ions that replace Al^{3+} ions in ruby, on the one hand, shorten the spin–lattice relaxation time T_1 for ^{27}Al and, on the other, provide a mechanism to polarize the ^{27}Al positively or negatively with respect to the direction of the strong magnetic field $\mathbf{B}_0$. The experimental optimum for short relaxation and strong polarization was found in a specimen cut from a single crystal with a Cr^{3+} concentration of nominally 0.02%. The efficiency of the DNP technique has been tested by comparing enhanced NMR signals with those taken at the lattice temperature θ_L .⁶ The largest enhancement of about 400, corresponding to a nuclear spin polarization of about 17%, has been observed at $\theta_L = 1.9 \text{ K}$ for a crystal orientation of about 61° between the c axis and $\mathbf{B}_0$. This is the standard orientation with which all our NMR laser experiments have been performed. At this angle, the two strongest ESR transitions coincide: the laser behavior is optimal. In addition, this particular crystal orientation yields an almost exponential FID below the laser threshold, as shown in Figure 2. This experimental fact reflects the anticipated Bloch dynamics in ruby under standard conditions.

In order to reach the NMR laser threshold, the nuclear spins have to be polarized in the direction opposite to $\mathbf{B}_0$. A negative spin polarization of the order of 10% is required, which corresponds to a negative spin temperature of some millikelvins. This condition is easily met at the lattice temperature of liquid helium when microwaves of frequency ω are supplied to the sample with ω near an ESR transition frequency ω_e of the Cr^{3+} impurity ions. Setting ω slightly above ω_e then leads to the required low, negative spin temperature. Thereby, microwave energy is absorbed and delivered to the Cr^{3+} – Cr^{3+} spin–spin system. Its spin temperature θ_{ss} rises to negative values: spin–spin order is thus greatly enhanced. Furthermore, since the ^{27}Al Zeeman splitting is smaller than the Cr^{3+} linewidth, the coupling of nuclear and electronic spins now allows exchange of energy between the electronic spin–spin and the nuclear Zeeman system. The nuclear Zeeman system is therefore effectively pumped by DNP to a negative spin temperature.

2.2 Dynamical Variables and Time Constants

In the single mode NMR laser, the active ^{27}Al spins may be considered as being members of a two-level system to which an averaged Bloch vector $\mathbf{M} = (M_x, M_y, M_z)$ can generally

be assigned.⁷ The three macroscopic variables (M_x, M_y, M_z) are the Cartesian components of the nuclear magnetization $\mathbf{M}$ characterizing the active spins. They refer to a coordinate system that is fixed in the laboratory, with z parallel to $\mathbf{B}_0$ and x parallel to the axis of the NMR coil. The vector ($M_x, M_y, 0$) represents the transverse component $\mathbf{M}_t$ of $\mathbf{M}$, which, in the radiating state, precesses about $\mathbf{B}_0$. The vector ($0, 0, M_z$) is the longitudinal component of $\mathbf{M}$. Its value is proportional to the population difference of the two Zeeman levels that are engaged in the radiative process.

Those nuclear Zeeman levels that are not involved in the single mode behavior play an important role in the storage of nuclear Zeeman energy that can be delivered to the active spins. These inactive spins form a separate energy reservoir, whose content is also controlled by the DNP pump. It acts as a buffer, thereby drastically reducing the fluctuations of the microwave pump. For our purposes, we can lump the microwave pump and the reservoir spins together. Thus we form an effective DNP pump system, to which we assign an operationally defined pump magnetization M_e . Here we imply that the effective DNP pump tends to equalize M_z and M_e .

We now assume that the dynamics of the three macroscopic variables (M_x, M_y, M_z) are governed by two characteristic time constants T_2 and T_e . There exist spin-spin interactions in ruby that dephase the collective motion of the nuclear spins. Thus the transverse nuclear magnetization $\mathbf{M}_t$ tends to decay with a characteristic dephasing time equal to the transverse relaxation time T_2 . The corresponding decay rate is $\gamma_\perp = 1/T_2$. However, spin-spin interactions among the nuclear ^{27}Al and the electronic Cr^{3+} spins in ruby also furnish a mechanism to transfer Zeeman energy among the spins, in particular, from the effective DNP pump system to the lasing spins. We have shown that a characteristic time constant T_e , the pump time, can be assigned to the effective DNP pump system.⁴ Hence the pump speed or pump rate is $\gamma_\parallel = 1/T_e$. One should note that this drastic simplification of the complicated spin and DNP pump dynamics in ruby is only justified for the special running conditions of the NMR laser when the variations of M_z are small—typically less than a few percent. In that situation, the pumping conditions remain stable; hence M_e is approximately constant. Under these circumstances, the relatively slow spin-lattice relaxation and DNP processes can be ignored: T_e then plays the role of an effective longitudinal relaxation time.

Two further macroscopic variables of the NMR laser are amplitude and phase of the coherent radiation field $\mathbf{B}(t)$, which is proportional to the current $J_L(t)$ in the NMR coil. The corresponding time constant is the ringing time T_R of the LC circuit. Its decay constant is $x = 1/T_R = \omega_c/2Q$, where $Q = R_p/\omega_c L$ is the quality factor of the NMR coil.

3 CONVENTIONAL BLOCH-TYPE LASER EQUATIONS

The dynamic equations for the macroscopic variables of the NMR laser are analogous to the Maxwell-Bloch equations of quantum optics. In order to obtain them, consider the oscillating radiation field $\mathbf{B}(t)$ acting on the nuclear spins. We retain only those components that rotate in the same sense as the precessing spins, and introduce a reference frame (u, v, z) that similarly rotates around $\mathbf{B}_0$ with frequency ω .

Accordingly, $\Delta\omega_a = \omega_a - \omega$ is called the NMR detuning, and $\Delta\omega_c = \omega_c - \omega$ represents the coil or cavity detuning. Although ω may be freely chosen, it is convenient to set $\omega = \omega_a = \omega_c$ for the tuned, free-running NMR laser. In the case of an externally driven NMR laser, we may set $\omega = \omega_d$, with ω_d the frequency of the injected field. The phase of the rotating frame is still free: we fix it by letting the u and x axes coincide at $t = 0$. Hence, we assume that the five macroscopic variables (M_u, M_v, M_z) and (B_u, B_v) of the single mode NMR system obey, in the rotating-frame representation, the conventional Bloch equations:⁸

$$\left. \begin{aligned} \dot{M}_u &= -\gamma_\perp M_u + \Delta\omega_a M_v - s^2 g B_v M_z \\ \dot{M}_v &= -\gamma_\perp M_v - \Delta\omega_a M_u + s^2 g B_u M_z \\ \dot{M}_z &= -\gamma_\parallel (M_z - M_e) + g(B_v M_u - B_u M_v) \end{aligned} \right\} \quad (1)$$

where $\gamma_\perp$ and $\gamma_\parallel$ are suitable decay and pumping constants that have been defined before, and s is a spin factor that has been introduced to account for the fictitious spin- $\frac{1}{2}$ nature of the ruby NMR laser when it is interpreted as a two-level system. Indeed, only two of the $2I + 1$ levels of the real system are relevant. For the special case $I = \frac{1}{2}$, we have $s = 1$. In general, s must be calculated from quantum mechanical rules.⁷ For the single mode ruby laser with ^{27}Al as a spin- $\frac{5}{2}$ system, s^2 takes the values 9, 8, or 5, depending on the chosen NMR mode ($\frac{1}{2}, -\frac{1}{2}$), ($\frac{1}{2}, \frac{3}{2}$) or ($\frac{3}{2}, \frac{5}{2}$), respectively. For our standard NMR mode, we have $s = 3$.

In order to complete the laser equations, the components $B_u(t)$ and $B_v(t)$ of the self-induced transverse radiation field $\mathbf{B}_t(t)$ must be expressed in terms of the parameters of the NMR LC circuit.⁴ To this end, we observe that

$$B_t(t) = \frac{\mu_0 N I(t)}{l} \quad (2)$$

with $B_t(t) = |\mathbf{B}_t(t)|$, where $I(t)$ is the current flowing in the NMR coil, which has length l and N windings. The relationship between the induced emf V_{ind} and the current I is given by Kirchhoff's law:

$$\ddot{I} + \frac{\omega_c}{Q} \dot{I} + \omega_c^2 I = \frac{1}{L} \dot{V}_{\text{ind}} \quad (3)$$

where $Q = R_p/\omega_c L$ is the quality factor of the coil and R_p is the effective Ohmic parallel resistance. From Faraday's induction law, we further have

$$V_{\text{ind}} = -\mu_0 \eta S N \frac{d}{dt} (M_u \cos \omega t + M_v \sin \omega t) \quad (4)$$

under the assumption that the nuclear magnetization inside the coil is homogeneous. The parameters η and S are the filling factor and the cross-section of the NMR coil, respectively.

Substituting equations (4) and (2) into equation (3) and assuming that our system satisfies the conditions

$$\begin{aligned} \dot{M}_t &\ll \omega M_t, & \max\{|\Delta\omega_c|, |\Delta\omega_a|\} &\ll \min\{\omega_a, \omega_c, \omega\} \\ \omega_c^2 &\gg \frac{\omega_c}{Q} & & \gg 1 \end{aligned} \quad (5)$$

the second derivative in equation (3) can be dropped. The laser field equations thus become

$$\left. \begin{aligned} \dot{B}_u &= -\kappa B_u + \Delta\omega_c B_v - \chi M_v \\ \dot{B}_v &= -\kappa B_v - \Delta\omega_c B_u + \chi M_u \end{aligned} \right\} \quad (6)$$

where the field decay constant $\kappa = 1/T_R$ and the coupling constant

$$\chi = \frac{1}{2}\mu_0\eta Q\kappa \quad (7)$$

have been introduced. The expression for χ has been obtained from the well-known relation $L = \mu_0 N^2 S/l$.

Equations (1) and (5) together constitute the conventional Bloch-type laser (CBL) model. In the standard case of single mode operation involving the levels $(-\frac{1}{2}, \frac{1}{2})$ with perfect tuning $\Delta\omega_c = \Delta\omega_a = 0$, they read

$$\left. \begin{aligned} \dot{M}_u &= -\gamma_\perp M_u - 9gM_z B_v \\ \dot{M}_v &= -\gamma_\perp M_v + 9gM_z B_u \\ \dot{M}_z &= -\gamma_\parallel(M_z - M_e) + g(B_v M_u - B_u M_v) \\ \dot{B}_u &= -\kappa B_u - \chi M_v \\ \dot{B}_v &= -\kappa B_v + \chi M_u \end{aligned} \right\} \quad (8)$$

4 EXTENDED BLOCH-TYPE LASER EQUATIONS

The CBL equations, equation (8), describe the behaviors of both the amplitude and phase of the transverse magnetization $\mathbf{M}_t$ and of the field $\mathbf{B}_t$ through their (u, v) components. If one is interested only in the amplitude dynamics, as in the forthcoming examples, the CBL model, equation (8), can be reduced to a set of only three differential equations by choosing a convenient phase of the rotating frame. For this purpose, we retain only the variables M_v , M_z , and B_u (notice that the discarded M_u and B_v behave exactly as $-M_v$ and B_u , respectively, apart from the initial condition) to obtain

$$\left. \begin{aligned} \dot{M}_v &= -\gamma_\perp M_v + 9gM_z B_u \\ \dot{M}_z &= -\gamma_\parallel(M_z - M_e) - gM_v B_u \\ \dot{B}_u &= -\kappa B_u - \chi M_v \end{aligned} \right\} \quad (9)$$

This three-dimensional system can be further written in the form of the Lorenz equations:⁹

$$\left. \begin{aligned} \dot{x} &= -\sigma(x - y) \\ \dot{y} &= -y + rx - xz \\ \dot{z} &= -bz + xy \end{aligned} \right\} \quad (10)$$

by introducing the dimensionless variables

$$x = \frac{3g}{\gamma_\perp} B_u, \quad y = -\frac{3g\chi}{\kappa\gamma_\perp} M_v, \quad z = \frac{9g\chi}{\kappa\gamma_\perp} (M_z - M_e) \quad (11)$$

The derivatives are taken with respect to the dimensionless time $\tau = t\gamma_\perp$. The parameters

$$\sigma = \kappa\gamma_\perp^{-1}, \quad r = \frac{9g\chi}{\kappa\gamma_\perp} |M_e|, \quad b = \gamma_\parallel\gamma_\perp^{-1} \quad (12)$$

have the values $\sigma = 4.875$, $r = 1.807$, and $b = 2 \times 10^{-4}$ (see Table 1), which do not allow for any chaotic behavior. The system always relaxes to one of the two asymptotically stable fixed points

$$x = y = x_0 = \pm\sqrt{b(r-1)}, \quad z = z_0 = r - 1 \quad (13)$$

with a decay constant $\gamma_{\text{rel}} = \frac{1}{2}b$ and a frequency $\omega_{\text{rel}} = \sqrt{2x_0^2 - \frac{1}{4}b^2} = 1.797 \times 10^{-2}$. In physical units, they correspond to $\frac{1}{2}\gamma_\parallel \approx 2.4 \text{ s}^{-1}$ and $\nu_{\text{rel}} \approx 67.7 \text{ Hz}$.

Table 1 Experimentally Determined NMR Laser Properties for Standard Running Conditions; the Numerical Values are Used to Calculate the System Parameters of the EBL Model

Gyromagnetic ratio	g	$6.97 \times 10^7 \text{ s}^{-1} \text{ T}^{-1}$
Lattice temperature	T	4.2 K
Quality factor	Q	330
Static NMR field	B_0	1.109 T
Laser frequency	ν	$12.3 \times 10^6 \text{ Hz}$
Pump magnetization	M_e	-0.78 A m^{-1}
Threshold magnetization	M_k	0.436 A m^{-1}
Pump factor	r	1.79
Longitudinal pump rate	$\gamma_\parallel$	4.76 s^{-1}
Transverse decay rate	$\gamma_\perp$	$2.38 \times 10^4 \text{ s}^{-1}$
Nonexponential damping	α	0.607 m A^{-1}
Filling factor	η	0.42
Coupling constant	χ	$10.19 \text{ T m A}^{-1} \text{ s}^{-1}$
LC ringing constant	x	$1.17 \times 10^5 \text{ s}^{-1}$
Relaxation frequency	ν_{relax}	$60.5 \pm 0.5 \text{ Hz}$
Relaxation rate	γ_{relax}	$29.5 \pm 0.5 \text{ s}^{-1}$
Noise field	$\bar{B}_n$	$1.2 \times 10^{-12} \text{ T}$
Bandwidth	$\Delta\nu$	$37.2 \times 10^3 \text{ Hz}$
Length of wire	l	$1.30 \times 10^{-2} \text{ m}$
Radius of wire	R	$0.17 \times 10^{-3} \text{ m}$
Number of turns	N	30

Early investigations have shown that the CBL model reproduces only qualitatively the behavior of the real system. Therefore, we reconsidered critically the various steps of its derivation. The crucial modification has been suggested by the observation of laser transients towards the stable state after an external perturbation. Indeed, equation (1) accounts for just the exponential decay of the transverse nuclear magnetization $\mathbf{M}_t$ in the absence of the radiation field (FID), with the phenomenological relaxation time $T_2 = 1/\gamma_\perp$. Although deviations from this simple behavior are common in solids with complex spin-spin and spin-lattice interactions, the single ruby crystal of the NMR laser at standard orientation exhibits an FID that comes close to an exponential decay if the radiative feedback is small. However, the CBL model does not appropriately describe transients occurring after a perturbation of the free running laser conditions. Since this appears to be the effect of a nonlinearity in the relaxation mechanism, we assume the following extended Bloch equation to hold for the FID of the ruby NMR laser:^{10,11}

$$\dot{M}_t = -\gamma_\perp \left(1 + \frac{\alpha}{s} M_t\right) M_t \quad (14)$$

with $M_t = |\mathbf{M}_t|$. Here, α is an a priori unknown fit parameter, which can be considered as the coefficient of the lowest order term in a Taylor expansion modeling a nonexponential spin dephasing. Although the correction term $\alpha M_t/s$ is of the order of 10^{-3} , the new relaxation rule dramatically improves the accuracy of the model. It has to be remarked that there exists at present no quantitative theory that could explain the assumption in equation (14). Corrections of this type remain heuristic for the time being. However, since $\mathbf{M}_t$ is closely related to $\mathbf{B}_t$, the new contribution might be interpreted as a dephasing effect caused by the radiation field.

The complete extended Bloch-type laser (EBL) model, in the rescaled variables of Equation (11), takes the form

$$\left. \begin{aligned} \dot{x} &= -\sigma(x - y) \\ \dot{y} &= -y(1 + ay) + rx - xz \\ \dot{z} &= -bz + xy \end{aligned} \right\} \quad (15)$$

where

$$a = \frac{\alpha \kappa \gamma_{\perp}}{9g\chi} \approx 0.262 \quad (16)$$

Finally, by further introducing the variables

$$X = \frac{x}{x_0}, \quad Y = \frac{y}{x_0}, \quad Z = \frac{z - z_0}{x_0} \quad (17)$$

and the new time $\tau' = \tau x_0$, we obtain

$$\left. \begin{aligned} \dot{X} &= -\sigma'(X - Y) \\ \dot{Y} &= -Y(c + aY) + X(c - Z) \\ \dot{Z} &= -\beta Z - 1 + XY \end{aligned} \right\} \quad (18)$$

where $\sigma' = \sigma/x_0 \approx 384 \gg 1$, $c = 1/x_0 \approx 79$, and $\beta = b/x_0 \approx 1.57 \times 10^{-2}$. The values of X , Y , and $|Z|$ remain in the range $[0, 3]$ under all conditions, including chaotic behavior. Hence, the term aY is clearly small compared with c . Moreover, the large value of σ' renders the adiabatic elimination of X possible, yielding

$$\left. \begin{aligned} \dot{Y} &= -Y(aY + Z) \\ \dot{Z} &= -\beta Z - 1 + Y^2 \end{aligned} \right\} \quad (19)$$

Notice that the variable Y never changes sign, since its derivative $\dot{Y}$ is proportional to Y itself: this is in agreement with the fact that Y represents the modulus of the transverse magnetization vector $\mathbf{M}_t$.

5 BASIC TEST OF THE EBL MODEL

In order to test the efficiency of the two available models for the NMR laser, it is necessary to have good knowledge and control of the system parameters. Fortunately, the NMR laser is one of the rare nontrivial many body systems where all relevant parameters can be determined with good accuracy. Some of them may be measured directly (Q factor and laser frequency); the others (filling factor, decay and pumping constants, etc.) can be obtained indirectly, either by fitting the laser response after a suitable perturbation, or by performing appropriate supplementary NMR measurements. Table 1 displays the parameter values that characterize the ruby NMR laser at the temperature of liquid helium. Owing to the reliability of these measurements, any discrepancy between the CBL and EBL models that lies within the experimental resolution is to be attributed to qualitative differences in the dynamics.

We first discuss the effect of the inclusion of the new parameter α in the EBL model on the relaxation of the transverse magnetization by means of a controlled Q switching technique. The laser is first allowed to relax to M_t^s with an initial quality factor Q . Then, at some later time, the quality factor is abruptly lowered to a value Q_e (Q quenching), which is kept constant for a time T_q until the original value Q is restored. The output voltage $v(t) \propto M_v(t)$ is recorded thereafter.

If the laser action is completely quenched in the interval T_q (i.e., $Y \approx 0$), the subsequent laser pulses, followed by the relaxation to the fixed point M_t^s , are triggered by the noise fluctuations of the field in the NMR coil. This observation shows that a quantitative test of the model can be made only

Figure 3 Laser transients $v(t)$ as obtained from experiment (a) and from numerical simulations (b), after Q quenching. The quenching time was $T_q = 2$ ms. In (b), the outcome of the EBL model (solid line, $\alpha = 0.607$ m A $^{-1}$) may be compared with that of the CBL model (dotted, $\alpha = 0$). Notice the striking similarity between the EBL result and experiment

by taking noise explicitly into account. It is assumed that the major source is due to the thermal noise current in the coil. Its rms contribution $\bar{B}_n$ to the field at the absolute temperature T is given by

$$\bar{B}_n = \sqrt{\frac{\mu_0 k_B T Q \Delta \nu}{IR^2 2\pi^2 \nu_a}} \quad (20)$$

where k_B is Boltzmann's constant, $\Delta \nu$ the LC circuit bandwidth, ν_a its resonance frequency, and R the radius of the wire. Inserting realistic numbers yields $\bar{B}_n \approx 4.7 \times 10^{-12}$ T. Hence, the transients can be numerically generated by turning equation (6) into Langevin equations with two additive Gaussian noise terms with amplitude $\bar{B}_n$. Experimental and computed transient signals are reported in Figure 3(a) and (b), respectively. The numerical simulation has been performed with the CBL (dotted line) and EBL (solid line) models, the latter yielding the best fit with the real data for $\alpha \approx 0.607$ m A $^{-1}$. The quenching time was $T_q = 20$ ms. The agreement with experiment is evident for the EBL model, whereas the CBL model grossly fails to reproduce both the amplitude decay and the oscillation frequency (given by γ_{rel} and ν_{rel} , respectively). These results illustrate the enormous effect of the small correction term $\alpha M_v/3 \approx 3 \times 10^{-3}$ on the laser dynamics. That observation is in great contrast to the behavior way below the laser threshold, as depicted in Figure 4, showing an FID and its fit with the CBL and EBL models. The

Figure 4 Amplitude of the FID below laser threshold and its fit with the EBL (solid line, $\alpha = 0.607 \text{ m A}^{-1}$) and CBL (dash-dotted line, $\alpha = 0$) models; error bars experimental results. Note the extremely weak dependence on α

correction term α has a negligible effect on dephasing during the FID.

6 THE NMR LASER AS A SMALL SIGNAL DETECTOR

The preceding sections have shown that the NMR laser under standard conditions is restricted to a two-dimensional phase space. Within its accessible parameter space, the dynamics are governed by an attracting fixed point (constant amplitude). However, if an external drive is applied, for example in the form of a sinusoidal modulation of a system parameter, the additional degree of freedom induces bifurcations in the forced limit cycle behavior that may even lead to chaos. Experimentally, this has been realized by varying a system parameter p in time according to $p(t) = p_0(1 + A_p \cos \omega_p t)$, where the modulation frequency $\nu_p = \omega_p/2\pi$ is chosen in the range [20, 150] Hz, i.e., close to the relaxation frequency $\nu_{\text{rel}} \approx 67.7 \text{ Hz}$ of the free running laser. For a fixed value of ω_p , bifurcations occur at the critical amplitudes $A_c^{(n)}$, $n = 1, 2, 3, \dots$

We now want to discuss the remarkable amplification properties of the parametrically modulated laser (PML) near one of its bifurcation points when an additional external signal is injected. This very general feature of nonlinear systems may then be used to detect small external signals.^{12,13} In order to apply this small-signal detection method, we may start from the PML with a modulation signal $S_p = A_p \sin \omega_p t$. Then, we supply a second, but small, signal $s_i = \alpha_i \sin \omega_i t$ to the PML in order to generate an additional frequency in the system. For selected values of A_p , ω_p , and ω_i , we observe a strong nonlinear coupling of s_i with S_p , thus providing a mechanism for a frequency-selective small-signal detection scheme. We call S_p and s_i the parametric pump and input signals of this parametrically double modulated laser (PDML).

Figure 5 Experimental oscillations of the NMR laser output: (a) with the pump signal S_p on (PML), and A_p below but near $A(1)/c$; (b) with the pump and the input signal s_i on (PDML), and $\omega_i \approx 1/2\omega_p$. Note the strong amplification of the input signal where $a_i \ll A_p$

In the PML mode ($s_i = 0$), A_p and ω_p are adjusted such that a sequence of period-doubling bifurcations occurs. In keeping ω_p fixed, A_p is set close to, but below, one of the observed critical values $A_c^{(n)}$, $n = 1, 2, 3, \dots$, for the instabilities. The PML output oscillates under the forcing signal S_p with constant amplitude and the fundamental frequency $\omega_p/2^{n-1}$, as shown in Figure 5(a), for $n = 1$. Thus, we have a stable limit cycle behavior. When s_i is switched on, the output will change its amplitude periodically, as depicted in Figure 5(b). This characteristic form of the time behavior suggests the following procedure to define an operational response function for the PDML as a small-signal detector near a period-doubling bifurcation: first, measure the differences between the heights of consecutive peaks (high–low); second, determine the average amplitude ΔS of these time-dependent differences. Since ΔS is obviously a measure of the strength of the dynamical precursor of the nearby bifurcation ($\omega_p \rightarrow \frac{1}{2}\omega_p$), one may call ΔS the experimental sensitivity of the system to the input $s_i = a_i \sin \omega_i t$ and $\Delta S(\omega_i)$ the corresponding experimental response function. That definition then can readily be extended to higher bifurcations ($\omega_p/2^{n-1} \rightarrow \omega_p/2^n$), where ΔS refers to peaks that differ in time by $2^{n-1}T_p$, the period of the pump signal $S_p = A_p \sin \omega_p t$. Typically, $\Delta S(\omega_i)$ peaks at certain frequencies, the lowest being the fractional frequency $\omega_p/2^n$. A strong peaking, and therefore a high detection sensitivity for s_i , requires a pump frequency ω_p of the order of ω_{relax} and a pump amplitude A_p as close as possible to one of the instability points $A_c^{(n)}$.

To demonstrate PDML characteristics, one measures $\Delta S(\omega_i)$ by means of a strobing technique for the proper testing of the PDML output. There, the signal is stroboscopically sampled at times that differ by $2^{n-1}T_p$. The phase of the discrete timing is adjusted to render maximum sensitivity for $\omega_i = \omega_p/2^n$. The discrete output values are digitized and stored in a computer; ΔS is then calculated and displayed. In a run, the computer is used also to control the scan of ω_i in small quasi-adiabatic steps. In Figure 6, we depict the outcome of two typical runs to measure $\Delta S(\omega_i)$. The two cases correspond to the frequency setting $\omega_p \approx 2\omega_{\text{relax}}$. In

Figure 6 Stroboscopically measured small-signal detection sensitivity, showing strong maxima at defined input frequencies ω_i

run (a), A_p was set below the instability point $A_c^{(1)}$, where the first experimental period-doubling ($\omega_p \rightarrow \frac{1}{2}\omega_p$) occurs. In run (b), A_p was increased to almost $A_c^{(2)}$, where the second period-doubling ($\frac{1}{2}\omega_p \rightarrow \frac{1}{4}\omega_p$) sets in. There is a remarkable difference between runs (a) and (b). Whereas (b) yields distinct peaks at

$$\omega_i \rightarrow \frac{1}{4}\omega_p, \quad \frac{3}{4}\omega_p, \quad \frac{5}{4}\omega_p, \quad \dots, \quad (21)$$

(a) yields a single peak at $\omega_i \rightarrow \frac{1}{2}\omega_p$ only. The results of run (b) indicate the presence of a true period-doubling bifurcation at $A_c^{(2)}$ with a typical response function $\Delta S(\omega_i)$ as predicted. In contrast to run (b), run (a) leads to the conclusion that the instability at $A_c^{(1)}$ does not reflect a bifurcation. More likely, the PML at $A_c^{(1)}$ jumps discontinuously from one stable attractor to another that has twice that period. In this view, the different results of Figure 6 suggest the use of the PDML scheme to study also the nature of instabilities in nonlinear systems.

Extensive numerical simulations of the PDML response are in good agreement with observations. The PDML has been

used to observe weak NMR signals from an external source. Its potential as an NMR detector has yet to be exploited.

1 INTRODUCTION

Since its invention, NMR spectroscopy has developed from a technique for studying physical phenomena such as magnetism into a tool for acquiring information about molecules in chemistry and biology. Furthermore, it was pointed out early on in 1955, almost as an anecdote, that nuclear spins could also be used for storing information using spin echoes.¹

This insight beautifully illustrated a notion that was developed in a very different context: information is physical and cannot exist without a physical representation.² In recent decades, the relationship between physics and information has been revisited from a new perspective: could the laws of physics play a role in *how* information is processed? The answer appears to be yes. If information is represented by systems such as nuclear spins governed by the laws of quantum mechanics, an entirely new way of doing computation, quantum computation (QC), becomes possible. Quantum computing is not just different or new; it offers an extraordinary promise, the capability of solving certain problems which are beyond the reach of any machine relying on the classical laws of physics.

The practical realization of quantum computers is still in its infancy. Interestingly, over 40 years after the initial suggestion of using spins to represent (classical) information, NMR spectroscopy has become the workhorse for experimental explorations of quantum information processing.

In this article, we first explain how quantum computers work and why they could solve certain problems so much faster than any classical computer. Next, we describe how quantum computers can be implemented using nuclear magnetic resonance (NMR) techniques and what is involved in designing and implementing QC pulse sequences, preparing a suitable initial state and interpreting the output spectra. We close with an overview of the state of the art and the prospects for NMRQC and other QC implementations.

Good reviews of quantum computation and information can be found in Refs.^{3–5} A specialized review of and a good introduction to NMRQC are given in Refs.^{6,7} respectively.

2 QUANTUM COMPUTATION

2.1 INEPT as a Computation

We start from a familiar place for many NMR spectroscopists, the INEPT pulse sequence (see **INEPT**, Volume 4). This sequence was designed to transfer polarization from a high γ nucleus to a low γ nucleus. However, it can also be viewed as a *logic gate* (Figure 1) which flips one spin conditioned upon the orientation of a neighboring spin.

If we arbitrarily assign “0” to a spin up and “1” to a spin down, we can think of spin-1/2 nuclei as bits in a digital computer. We remind the reader that bits (“0” or “1”) can be used to represent numbers in a similar way to decimal numbers (“0” through “9”). In decimal representation, 503 means $3 \times 10^0 + 0 \times 10^1 + 5 \times 10^2$; similarly, in binary representation, 1101 means $1 \times 2^0 + 0 \times 2^1 + 1 \times 2^2 + 1 \times 2^3$ (which corresponds to the number 13 in decimal representation). All computers today process information in binary representation, and are able to rapidly perform multiplication and division (repeated addition and subtraction) as well as the most complex computations, via a sequence of very simple, elementary operations, called logic gates, acting on just one or two bits at a time.

In this binary framework, the INEPT sequence corresponds to an elementary two-bit operation known as the controlled-NOT or for short CNOT gate within the phase corrections discussed in Section 3.1. The CNOT gate performs a NOT operation on a second bit, flipping it from “0” to “1” or from “1” to “0”, if and only if the value of a first bit is “1”. The input to the logic gate is the initial state of the spins, and the output is the final state of the spins. The four possible input values and the corresponding output values are tabulated in Figure 2.

The CNOT combined with single-spin rotations provides for a *universal* set of logic gates. This means that *any* computational task can be implemented using a sufficiently large number of nuclear spins simply by concatenating CNOTs and single-spin rotations in the proper way.^{8–10} In summary, spin-1/2 nuclei in a molecule can serve as bits in a computer, while pulses and delay times provide universal logic gates.

2.2 Quantum Parallelism

Everything we have discussed so far has been purely classical. The Bloch sphere picture of Figure 1 reinforces this

Figure 1 The evolution of one of two coupled heteronuclear spins during an INEPT type pulse sequence, when the other spin is up (solid line) or down (dashed line). The rotating frame is set on resonance with the first spin so there is no need to refocus chemical shift. The usual read-out pulse is left out. The same pulse sequence can be applied to two homonuclear spins using spin-selective pulses

Figure 2 (a) Input and output states for the INEPT pulse sequence and (b) for the corresponding CNOT gate

classical view of the spins; however, nuclear spins are quantum objects. In Dirac notation, the state of a spin can be denoted $|0\rangle$ for a spin in the ground state (along z), and $|1\rangle$ for a spin in the excited state (along $-z$), corresponding to the two classical values for a bit (“0” and “1”). Now, a spin along the x axis is in reality in a coherent superposition state of spin up and spin down, written as $(|0\rangle + |1\rangle)/\sqrt{2}$, while a spin along the y axis is in the state $(|0\rangle + i|1\rangle)/\sqrt{2}$, etc. A spin-1/2 particle is thus more complex than a classical bit. Any two-level quantum system, such as a spin-1/2 particle, can serve as a quantum bit (qubit).

The difference between the quantum and classical descriptions becomes clear as soon as more than one quantum particle is considered. For example, it is well known that the state of n interacting spin-1/2 cannot be described simply by n sets of coordinates on the Bloch sphere. In order to include phenomena such as multiple-quantum coherence, we need recourse to $4^n - 1$ real numbers in the product operator expansion or equivalently to density matrices of dimension $2^n \times 2^n$. Furthermore, the evolution of a closed system of n spins can only be described by $2^n \times 2^n$ unitary matrices (see **Liouville Equation of Motion**, Volume 4). The number of degrees of freedom that need to be specified in a classical description of the state and dynamics of n coupled spins thus increases exponentially with the number of spins.

Richard Feynman proposed in 1982 that the exponential complexity of quantum systems might be put to good use in simulating the dynamics of another quantum system,¹¹ a task which requires exponential effort on a classical computer. David Deutsch extended and formalized this idea in 1985, and introduced the notion of “quantum parallelism”.¹²

Consider a (classical) logic gate which implements a function f with one input bit x and one output bit $f(x)$. If $x = 0$, the gate will output $f(0)$; if $x = 1$, the output will be $f(1)$. The analogous quantum logic gate is described by a unitary operation which transforms a qubit as

$$|0\rangle \mapsto |f(0)\rangle \quad \text{and} \quad |1\rangle \mapsto |f(1)\rangle$$

However, due to the possibility of preparing coherent superposition states and to the linearity of quantum mechanics, the same gate also performs the transformation

$$\frac{|0\rangle + |1\rangle}{\sqrt{2}} \mapsto \frac{|f(0)\rangle + |f(1)\rangle}{\sqrt{2}}$$

In this sense, it is possible to evaluate $f(x)$ for both input values in one step. Next consider a different logic gate which implements a function $g(x)$ with two input bits. We can prepare each qubit in a superposition of “0” and “1”. Formally, the state of the joint system is then written as $(|0\rangle + |1\rangle) \otimes (|0\rangle + |1\rangle)/2$. Leaving out the tensor product symbol as well as any normalization factors, the state can be written as $(|0\rangle + |1\rangle)(|0\rangle + |1\rangle)$, or $|0\rangle|0\rangle + |0\rangle|1\rangle + |1\rangle|0\rangle + |1\rangle|1\rangle$, which is further abbreviated to $|00\rangle + |01\rangle + |10\rangle + |11\rangle$. Therefore, a set of two spins can be in a superposition of the four states “00”, “01”, “10” and “11”. A quantum logic gate implementing $g(x)$ then transforms this state as

$$|00\rangle + |01\rangle + |10\rangle + |11\rangle \mapsto |g(00)\rangle + |g(01)\rangle + |g(10)\rangle + |g(11)\rangle$$

Thus the function has been evaluated for the four possible input values in parallel. In general, a function of n qubits implemented on a quantum computer can be evaluated for all 2^n input values in parallel. In contrast to classical computers, for which the number of parallel function evaluations increases at best linearly with their size, the number of parallel function evaluations grows exponentially with the size of a quantum computer (the number of qubits).

Obviously, this is true only so long as the coherent superposition states are preserved throughout the computation. This means that the computation should be completed before quantum coherence is lost due to “decoherence” processes (in NMR, spin–spin and spin-lattice relaxation; see **Relaxation: An Introduction**, Volume 6). Since some degree of decoherence is unavoidable, practical quantum computers appeared virtually impossible to build, until quantum error correction was conceived, as discussed in Section 2.4.

Even if the coherence time is long compared to the duration of a typical logic gate and quantum error correction is employed, can we really access the exponential power exhibited by quantum systems? The postulates of quantum mechanics dictate that a measurement – which induces instantaneous and complete decoherence – of a qubit in a superposition state $|f(0)\rangle + |f(1)\rangle$ will give either “ $f(0)$ ” or “ $f(1)$ ”, with equal probabilities. Similarly, after doing 2^n computations all at once, resulting in a superposition of 2^n output values, measurement of the quantum bits randomly returns a single output value. A more clever approach is thus needed exploiting quantum parallelism requires the use of quantum algorithms.

2.3 Quantum Algorithms

Special quantum algorithms allow one to take advantage of quantum parallelism in order to solve certain problems in far fewer steps than is possible classically. When comparing the capability of two computers to solve a certain type of problem, the relevant criterion is not so much what resources (time, size, signal-to-noise ratio, ...) are required to solve the problem but rather how quickly the required resources grow with the problem size.

A particularly important criterion is whether the required resources increase exponentially or polynomially with the problem size. Exponentially difficult problems are considered intractable; they become impossible to solve when the problem size is large. In contrast, polynomially difficult problems are considered tractable. The interest in quantum computing is based on the fact that certain problems which

appear intractable (resources grow exponentially with problem size) on any classical computer are tractable on a quantum computer.

This was shown in 1994 by Peter Shor, almost 10 years after Deutsch introduced quantum parallelism. Shor's quantum algorithm¹³ allows one to find the period of a function exponentially faster than any classical algorithm. The importance of period-finding lies in that it can be translated, using some results from number theory, to finding the prime factors of integer numbers, and thus also to breaking widely used cryptographic codes. These codes are based precisely on the fact that no *efficient* classical algorithm is known for period-finding or factoring, i.e., the effort required to factor a number on classical computers increases exponentially with the number of digits of the integer to be factored. In contrast, Shor's algorithm is efficient: on a quantum computer, the effort to factor an integer increases only polynomially (to be precise, the third power) with the number of digits of the integer. As a result, while factoring a 1000-digit number is believed to be beyond the reach of any machine relying on the classical laws of physics, such a feat could be accomplished on a quantum computer.

The first quantum algorithm was invented by Deutsch and Jozsa¹⁴ in 1992. This algorithm allows a quantum computer to solve with certainty an artificial mathematical problem known as Deutsch's problem. Even though this algorithm does not have much application, it is historically significant as it provided the first steps towards Shor's algorithm, and because it is a simple quantum algorithm that can be experimentally tested.

Another class of quantum algorithms was discovered in 1996 by Lov Grover. These algorithms¹⁵ allow quadratic speed-ups of certain search problems, for which there is no better approach classically than to try all L candidate solutions one at a time. A quantum computer using Grover's algorithm needs to make only $\sqrt{L}$ such trials. Even though this speed-up is only quadratic rather than exponential, it is still significant.

The last currently known application of quantum computers lies in simulating other quantum systems,¹⁶ as Feynman conjectured. Even a computer consisting of no more than a few dozen quantum bits could outperform the fastest classical computers in solving important physics problems, such as calculating the energy levels of an atom.¹⁷

In the remainder of this section, we briefly review the structure of Shor's algorithm, because it is so important and at the same time gives good insight into how quantum computing works (for a more detailed explanation, see Refs.^{4,13}). The crucial step in Shor's factoring algorithm is the use of the quantum Fourier transform (QFT) to find the period r of the function $f(x) = a^x \bmod M$, which means $f(x)$ is the remainder after division of a^x by M , where M is the integer to be factored, and a is an integer which is more or less randomly chosen.^{4,13}

The QFT performs the same transformation as the (classical) fast Fourier transform (FFT), but can be computed exponentially faster. As always, we do not have access to all the individual output values; the QFT merely allows us to *sample* the FFT but we will see that this suffices for period-finding. The FFT_N takes as input a string of N complex numbers x_j and produces as output another string of N complex numbers

y_k , such that

$$y_k = \frac{1}{\sqrt{N}} \sum_{j=0}^{N-1} x_j e^{2\pi i j k / N} \quad (1)$$

For an input string with numbers which repeat themselves with period r , the FFT_N produces an output string with period N/r , as illustrated in the following four examples for $N = 8$ (the output strings have been rescaled for clarity)

r	input string		output string	N/r	
8	1 0 0 0 0 0 0 0	$\mapsto$	1 1 1 1 1 1 1 1	1	(a)
4	1 0 0 0 1 0 0 0	$\mapsto$	1 0 1 0 1 0 1 0	2	(b)
2	1 0 1 0 1 0 1 0	$\mapsto$	1 0 0 0 1 0 0 0	4	(c)
1	1 1 1 1 1 1 1 1	$\mapsto$	1 0 0 0 0 0 0 0	8	(d)

If r does not divide into N , the inversion of the period is approximate. Furthermore, the FFT turns shifts in the locations of the numbers in the input string into phase factors in front of the numbers in the output string:

1 0 0 0 1 0 0 0	$\mapsto$	1 0	1 0	1 0	1 0	(e)
0 1 0 0 0 1 0 0	$\mapsto$	1 0	$-i$	0	-1 0	i 0 (f)
0 0 1 0 0 0 1 0	$\mapsto$	1 0	-1 0	1 0	-1 0	(g)
0 0 0 1 0 0 0 1	$\mapsto$	1 0	i 0	-1 0	$-i$ 0	(h)

The QFT performs exactly the same transformation, but differs from the FFT in that the complex numbers are stored in the amplitude and phase of the terms in a superposition state. The amplitude of the $|000\rangle$ term represents the first complex number, the amplitude of the $|001\rangle$ term the second number and so forth. For clarity, we will label the states $|000\rangle, |001\rangle, \dots, |111\rangle$ as $|0\rangle, |1\rangle, \dots, |7\rangle$. As an example, we see from (f) that the QFT transforms the state $|1\rangle + |5\rangle$ to the state $|0\rangle - i|2\rangle - |4\rangle + i|6\rangle$.

The QFT is incorporated in actual quantum algorithms as outlined in Figure 3. A first register (group of qubits) is prepared in a superposition of all its possible states. A second register is initialized to the ground state (for factoring a number M , the size of the second register must generally be at least $\log_2 M$ and the first register must be at least twice as large). For example, if register 1 has three qubits and register 2 has two qubits, the state of the system is prepared in

$$(|0\rangle + |1\rangle + |2\rangle + |3\rangle + |4\rangle + |5\rangle + |6\rangle + |7\rangle)|0\rangle \quad (2)$$

Figure 3 Schematic diagram of the main steps in quantum algorithms for period-finding

Then the function $f(x)$ is evaluated (in NMR by applying a pulse sequence, as discussed in Sections 2.1 and 3.1), where x is the value of the first register, and the output value $f(x)$ is stored in the second register. Since the first register is in an equal superposition of all $|x\rangle$, the function is evaluated for all values of x from 0 to 7 in parallel. For example, let $f(x) = 3$ for even x and $f(x) = 1$ for odd x , which means the period r is 2 (in real applications, we have a description of f but do not know r in advance). Evaluation of $f(x)$ then transforms the state of equation (2) to the state

$$\begin{aligned} &|0\rangle|3\rangle + |1\rangle|1\rangle + |2\rangle|3\rangle + |3\rangle|1\rangle \\ &+ |4\rangle|3\rangle + |5\rangle|1\rangle + |6\rangle|3\rangle + |7\rangle|1\rangle \\ &= (|0\rangle + |2\rangle + |4\rangle + |6\rangle)|3\rangle + (|1\rangle + |3\rangle + |5\rangle + |7\rangle)|1\rangle \end{aligned} \quad (3)$$

We pause to point out that this state is *entangled*, which means that it cannot be written as a product of single-qubit states. The state $|00\rangle + |01\rangle + |10\rangle + |11\rangle$ is an example of an unentangled state, because it can be written as $(|0\rangle + |1\rangle)(|0\rangle + |1\rangle)$, a product of single-qubit states. In contrast, $|00\rangle + |11\rangle$ is a simple example of an entangled state. Entanglement has no classical analogue and is believed to lie at the heart of the exponential speed-up offered by quantum computation.

In order to appreciate the role of the QFT, suppose we now measure the second register in equation (4) (this measurement can be left out but simplifies the explanation). The state of the first register will collapse to either

$$|0\rangle + |2\rangle + |4\rangle + |6\rangle \quad \text{or} \quad |1\rangle + |3\rangle + |5\rangle + |7\rangle \quad (5)$$

depending on whether the measurement of register 2 gave “3” or “1”. We see that all eight possible outcomes are still equally likely, so the result of a measurement does not give us any useful information. But if we apply the QFT, the first register will be transformed to

$$|0\rangle + |4\rangle \quad \text{or} \quad |0\rangle - |4\rangle \quad (6)$$

Now a measurement of the first register does give useful information, because only multiples of N/r are possible outcomes, in this example “0” and “4”.

This concludes the quantum part of the computation. From the measurement result, a classical computer can efficiently calculate the inverted period N/r , and thus also r , with high probability of success using results from number theory. Now that r is known, the factors of the integer M can be quickly computed from number theory as well, with high probability (the probability of success can be further increased by repeating the whole procedure a few times).

We close with two final remarks on quantum algorithms: (1) quantum computing cannot offer any speed-up for many common tasks, such as adding up two numbers or word processing, which can already be completed efficiently on a classical computer; and (2) there are many problems which take exponential effort on both quantum and classical computers. It would be somewhat disappointing from a practical viewpoint if no other applications were found; however, our understanding of the connection between physics and information and computation has already changed dramatically.

2.4 Quantum Error Correction

Any quantum computation must be completed within the coherence time, T_2 and T_1 in NMR, as pointed out in Section 2.2. T_1 and T_2 processes alter the state of the qubits and are therefore a source of errors. For many years, this requirement led to widespread pessimism about the practicality of quantum computers. In 1995, however, Peter Shor and Andrew Steane independently discovered quantum error correction^{46,47} and showed that it is possible to correct for truly random errors caused by decoherence.

This came as quite a surprise, because quantum error correction had to overcome three important obstacles: (1) the no-cloning theorem, which states that it is not possible to copy unknown quantum states;⁵ (2) measuring a quantum system affects its state; and (3) errors on qubits can be arbitrary rotations in Hilbert space, compared with simple bit flips for classical bits. Quantum error correction requires many extra operations and extra qubits (ancillae), however, which might introduce more errors than are corrected, especially because the effect of decoherence increases exponentially with the number of entangled qubits, in much the same manner that multiple quantum coherences decay exponentially faster than single quantum coherences. Therefore, a second surprising result⁴⁸ was that provided the error rate (probability of error per elementary operation) is below a certain threshold, and given a fresh supply of ancilla qubits in the ground state, it is possible to perform arbitrarily long quantum computations.

The threshold error rate is currently estimated⁴⁸ to be about 0.001%. The actual error rate in NMRQC is approximated by $1/2JT_2$, where $2JT_2$ is roughly the number of operations that can be computed within the coherence time. For small molecules the error rate is typically on the order of 0.1–1%, two to three orders of magnitude too high. A remarkable implication of quantum error correction, however, is that if (1) a molecule is found which achieves the threshold error rate; and (2) select spins can be fully polarized, both T_1 and T_2 could in principle be infinitely lengthened by applying an error correction pulse sequence.

3 NMR QUANTUM COMPUTERS

3.1 Pulse Sequence Design

At first sight, the translation of abstract quantum algorithms or function evaluations into actual pulse sequences may appear obscure: However, systematic techniques^{18,19} exist to make pulse sequence design relatively straightforward. The starting point is that: each quantum algorithm can be described by a sequence of transformations under unitary operators.

Such unitary transformations represent rotations in Hilbert space (a multidimensional extension of the Bloch sphere). Examples of unitary transformations are evolution during RF pulses and free evolution under the system Hamiltonian; relaxation processes give rise to nonunitary transformations. Once the desired unitary operators have been identified, arbitrary unitary operators can be translated into sequences of single-qubit rotations and CNOT gates.

These building blocks can be readily implemented in NMR (see Section 3.2). Decompositions into other sets of elementary gates are also possible, and can be helpful in simplifying the pulse sequences.^{20,38} In any case, it is crucial that the duration

of the pulse sequence design process as well as the length of the resulting pulse sequence do not increase exponentially with the problem size.

We now point out two important distinctions between QC and conventional pulse sequences. On the one hand, QC sequences must be more general: QC sequences must perform the desired transformation for arbitrary input states. In contrast, conventional sequences are often designed assuming a particular input state. As a first example of this difference, the sequence of Figure 1 assumes that both spins are in Zeeman states, i.e., aligned along $\pm z$. It implements the unitary operator

$$\hat{U}_{\text{INEPT}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & i & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & -i & 0 \end{pmatrix} \quad (7)$$

which is similar to but different from the unitary operator for the CNOT gate, defined as

$$\hat{U}_{\text{CNOT}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \end{pmatrix} \quad (8)$$

implemented, for example, by $90_z^a 90_{-z}^b 90_x^b 1/2 J_{ab} 90_{-y}^b$.

As a second example, consider the so-called Hadamard gate, defined as

$$\hat{U}_{\text{Had}} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix} \quad (9)$$

This gate creates a superposition state starting from a basis state: it transforms $|0\rangle$ to $|0\rangle + |1\rangle$ (z to x in the Bloch sphere) and $|1\rangle$ to $|0\rangle - |1\rangle$ ($-z$ to $-x$). At first sight, this transformation could be done simply via a 90_y pulse. However, the unitary operator for 90_y

$$\hat{U}_{90_y} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix} \quad (10)$$

is different from $\hat{U}_{\text{Had}}$; e.g., applying $\hat{U}_{\text{Had}}$ twice has no net effect, but applying $\hat{U}_{90_y}$ twice produces U_{180_y} . A possible sequence to implement $\hat{U}_{\text{Had}}$ exactly is $90_y 180_x$.

On the other hand, QC sequences can be more specific: QC sequences can be specialized for a specific molecule using full knowledge of its spectral properties. In contrast, conventional sequences must work for any molecule, because the spectral properties of the molecule are usually not known in advance. Exact knowledge of the chemical shifts and J -coupling constants allows one not only to greatly simplify the pulse sequences, but also to achieve much more accurate unitary transformations than would otherwise be possible.

Finally, while systematic procedures exist to design a pulse sequence, there is a need to develop tools to find the pulse sequence of the shortest duration and with the fewest RF pulses. Even small-scale quantum computations easily involve tens to hundreds of gates acting on multiple spins and precise control of the spin dynamics is difficult to maintain throughout such long sequences of operations, as shown in the next section.

3.2 Implementation of Computations

The implementation of quantum computations with NMR can be based on single-spin rotations and CNOT gates, since any quantum algorithm can be translated into these building blocks. Although these elementary operations appear quite easy to implement, the requirements for precision in QC experiments are unusually high, due to the large number of pulses and the quantitative nature of the information contained in the output spectra.

Implementation of accurate *single-spin rotations* about an axis in the x - y plane is relatively easy in heteronuclear molecules; yet, it can be very demanding for homonuclear spin systems because spin selectivity requires longer pulses resulting in considerable coupled evolution of the spins during the pulses.²¹ Clearly, some degree of homonuclear dynamics is unavoidable when more than a handful of qubits are involved.

We therefore begin by reviewing the requirements for pulse shaping²² (see **Selective Pulses**, Volume 7; **Shaped Pulses**, Volume 7). First, the magnetization corresponding to each of the lines in a multiplet must be rotated about exactly the same axis and over exactly the same angle, i.e., off-resonance effects due to line splitting must be removed. This requires self-refocusing shaped pulses or tailored composite pulses²³ (see **Composite Pulses**, Volume 2). Second, the effect of J -coupling between unselected spins must be removed, either during the pulse or later in the pulse sequence. Third, all pulses must be universal rotors, i.e., the rotation must be independent of the initial state of the spin. Fourth, the unselected spins must not be affected by the RF irradiation. This last requirement is difficult to satisfy because of transient Bloch–Siegert effects²⁴ which can result in substantial (tens of degrees) phase shifts of nearby unselected spins. However, it is possible to estimate and compensate for the Bloch–Siegert shift.^{25,26} Finally, simultaneous (as opposed to consecutive) pulses at two or more nearby frequencies are desirable in order to keep pulse sequences short, but transient Bloch–Siegert shifts greatly deteriorate such simultaneous rotations.^{27,28} Accurate simultaneous rotations at nearby frequencies can be achieved using a special correction technique.²⁹ Even then, simultaneous pulses on well-coupled spins may excite multiple quantum coherences.³⁰

There are a number of hardware requirements for successful execution of QC experiments. Good RF coil homogeneity is crucial in avoiding excessive signal attenuation and related errors. Furthermore, it is desirable that one frequency source and transmitter board per qubit be available. If there are more qubits than spectrometer channels, the carrier frequency must be jumped to the appropriate frequencies throughout the pulse sequence, or phase ramping techniques must be employed.³¹ A dedicated frequency source for each qubit also makes it easy to keep track of the rotating frame of each spin and apply all the pulses on any given spin with the correct relative phase. This removes the need for extra pulses to refocus chemical shift evolution.²² Alternatively, software rotating frames can be created by detailed bookkeeping of the time elapsed since the beginning of the pulse sequence such that the evolution of the rotating frame of any given spin with respect to the carrier reference frame can be calculated. The phases of the pulses throughout the pulse sequence, as well as the receiver phase, can then be adjusted accordingly.^{25,36} The same technique can be used to implicitly realize single-spin rotations about z .

Alternatively, z -rotations can be implemented using resonance offsets or composite pulses.²²

Two strategies exist for implementing CNOT gates (both assume first order spectra). If all the spins are mutually coupled, CNOT's can be realized via line-selective pulses which invert specific lines within a multiplet.¹⁰ In practice, it is usually more convenient to use pulse sequences such as the one demonstrated in Figure 1.^{8,10} For molecules with several coupled spins, the sequence of Figure 1 must be expanded with extra pulses to refocus undesired J -couplings; systematic methods exist to design efficient refocusing schemes.^{28,33,34} A CNOT between two uncoupled spins can be realized by swapping qubit states.^{32,35} For example, for a CNOT between two spins a and c which are not mutually coupled but which are both coupled to a third spin b , the procedure is as follows: apply a pulse sequence which swaps the state of a and b (via $\text{CNOT}_{ab} \text{CNOT}_{ba} \text{CNOT}_{ab}$), then perform a CNOT between b and c , and then swap a and b again. The net result is CNOT_{ac} ; spin b is unaffected. It is thus not necessary that all spins be pairwise coupled as long as the network of couplings includes all n spins.

An alternative to imposing the correct evolution on all the spins at all times, both for RF pulses and for CNOT-type gates, is to allow erroneous evolutions which will later be reversed. Such techniques have been highly successful in certain standard pulse sequences (see **Decoupling Methods**, Volume 3), but are much harder to develop for the nonintuitive and nontransparent QC pulse sequences. Nevertheless, it has been shown experimentally that a large degree of cancellation of erroneous evolutions is possible even in QC experiments: about 300 two-qubit gates involving over 1350 90° RF pulses have been successfully concatenated.³⁶ A general methodology designed to take advantage of this possibility has yet to be developed.

From this discussion, it will be clear that the selection of a suitable molecule is crucial for NMRQC. The desired properties are (1) sufficiently large chemical shifts for good addressability, (2) large coupling constants, while maintaining first-order spectra, for fast two-qubit gates (or a coupling network that matches the pattern of connectivities needed for the algorithm), and (3) long T_2 and T_1 in order to allow time to execute many logic gates. Furthermore, high γ nuclei are desirable for good sensitivity. More mundane but equally important requirements are that the molecule be stable, synthesizable, soluble and safe.

3.3 State Initialization

Apart from experiments designed to produce nonthermal spin polarizations, setting up a proper initial state for the nuclear spins is a concept worth revisiting for NMR spectroscopists. Since it is such a crucial step in quantum computing, this entire section is therefore devoted to state initialization.

Most quantum computations require a *pure* initial state, for example a set of fully polarized spins, in the state $|00\dots 0\rangle$. However, nuclear spins in thermal equilibrium at room temperature are in an almost totally random state: for typical magnetic field strengths, the ground ($|0\rangle$) and excited ($|1\rangle$) state probabilities differ by only about 1 part in 10^5 . The spins are then said to be in a *mixed* (nonpure) state. The polarization could be increased using hyperpolarization techniques (see **Optically Enhanced Magnetic Resonance**, Volume 5) but the state of the art is still very far from cooling nuclear spins into the ground state.

The conceptual breakthrough which made NMR quantum computation possible at room temperature was the concept of *effective pure* or *pseudo-pure* states:⁸⁻¹⁰ effective pure states are mixed states which produce the same signal as a pure state to within a scaling factor.

The signature of an effective pure state for n spins is that all but one of the 2^n populations are equal, and that no coherences are present. The density matrix then consists of an identity component and a pure state component. The identity density matrix is not observable in NMR since only population differences are observed, and furthermore does not transform under unitary evolutions ($UIU^\dagger = I$). Thus the visible signal is produced solely by the one distinct population, corresponding to a pure state. In product operator notation,³⁷ the effective pure ground state is proportional to $\hat{I}_z + \hat{S}_z + 2\hat{I}_z\hat{S}_z$ for two spins, to $\hat{I}_z + \hat{S}_z + \hat{R}_z + 2\hat{I}_z\hat{S}_z + 2\hat{I}_z\hat{R}_z + 2\hat{S}_z\hat{R}_z + 4\hat{I}_z\hat{S}_z\hat{R}_z$ for three spins, and so forth. Figure 4 shows how the effective pure state preparation is manifest in the spectrum of one of five coupled spins. A characteristic of effective pure (basis) states is that only one line survives in each multiplet.

Three methods are known for preparing effective pure states starting from thermal equilibrium.

- (1) *Logical labeling*^{8,38} consists of applying a pulse sequence which rearranges the thermal populations such that a subset of the spins is in an effective pure state, conditioned upon the state of the remaining spins. Then the computation is carried out within this embedded subsystem.³⁹

Figure 4 (a) Spectrum of pentafluorobutadienyl cyclopentadienyldicarbonyliron complex in thermal equilibrium. (b) The same spectrum after preparing an effective pure state $|00000\rangle$. (Reproduced from Ref.²⁶ by permission of the American Physical Society)

For example, the Boltzman populations for the states $\{|000\rangle, |001\rangle, |010\rangle, |011\rangle, |100\rangle, |101\rangle, |110\rangle, |111\rangle\}$ for a homonuclear three-spin system deviate from the uniform background by $\{3a, a, a, -a, a, -a, -a, -3a\}$ respectively, where

$$a = \frac{1}{2^n} \frac{\hbar\omega}{2k_B T} \ll 1$$

After rearranging the populations for the eight spin states as $\{3a, -a, -a, -a, a, a, a, -3a\}$, the last two qubits are in an effective pure state conditioned upon the first qubit being $|0\rangle$. As the total number of qubits n in the molecule increases, the relative fraction of effective pure qubits goes to 1, but the preparation sequence becomes complex quite rapidly for large n and the signal strength scales as $n/2^n$.

- (2) *Temporal averaging*⁴⁰ is similar to phase cycling (see **Phase Cycling**, Volume 6), since it consists of adding up the spectra of multiple experiments. However, instead of changing just the phase of some pulses, each experiment starts off with a different state preparation sequence which permutes the populations. For two heteronuclear spins, adding together three experiments which yield respective population deviations $\{a, b, -b, -a\}$, $\{a, -b, -a, b\}$ and $\{a, -a, b, -b\}$ is equivalent to performing an experiment with population deviations $\{3a, -a, -a, -a\}$. For arbitrary n , at least $(2^n - 1)/n$ experiments are needed,²⁶ since the effective pure state is made up of $2^n - 1$ product operator terms and the starting state, thermal equilibrium, contains n terms.
- (3) *Spatial averaging*¹⁰ uses a pulse sequence containing magnetic field gradients (see **Field Gradients & Their Application**, Volume 3) to equalize all the populations but the ground state population. Only one experiment is involved, but the preparation sequence quickly becomes unwieldy for large spin systems and the signal strength decreases exponentially with n .

To date, temporal and spatial averaging have been the most popular choices for preparing effective pure states. Several hybrid schemes^{25,40} have also been developed which trade off complexity of the preparation steps for the number of experiments. Nonetheless, all these state preparation schemes have in common that creating effective pure states incurs an exponential cost either in the signal strength or in the number of experiments involved.

Such an exponential overhead is of course not tolerable for quantum computations. The reason for this cost is that effective state preparation techniques simply select out the signal from the ground state population present in thermal equilibrium, and the fraction of molecules in the ground state is proportional to $n/2^n$.

A significant breakthrough by Schulman and Vazirani resulted in a method to cool a subset of the spins in a molecule down to the ground state without any exponential overhead.^{41,42} The idea is to redistribute the entropy of the spins so that some have zero entropy (pure state) while the entropy of the remaining spins increases. In a sense, this method is simply a polarization transfer scheme. Surprisingly, both the length of the cooling pulse sequence and the number of spins that must be sacrificed increase only about linearly with the number of pure spins desired. Furthermore, the cooling algorithm approaches the entropic bound in the limit

of large numbers of spins. However, with initial polarization $\alpha \ll 1$, a molecule with at least k/α^2 spins is needed to obtain k pure spins. This method is therefore impractical when starting from equilibrium at room temperature, with $\alpha \approx 10^{-5}$. Nevertheless, a combination of hyperpolarization techniques and the Schulman–Vazirani scheme may some day become practical. In any case, despite the exponential cost incurred when preparing effective pure states, the highly random initial state represents *no fundamental* obstacle to scalable quantum computation.

3.4 Read-out

In NMR spectroscopy, only one nucleus is traditionally observed. In QC, however, the concept of a single observe channel and one or more decoupler channels does not apply: the output of a quantum computation is the final state of one or several spins. The final states of each of the output spins must thus be read out.

If each of the output spins ends up in $|0\rangle$ or $|1\rangle$ (or in reality in the effective pure state corresponding to $|0\rangle$ or $|1\rangle$), the answer can be read-out directly by applying a pulse which rotates the spin from $\pm z$ to $\pm x$. With properly referenced receiver phase settings, the spectrum for each output spin then consists of either absorption or emission lines, indicating whether the output value of the corresponding bit is “0” or “1” (Figure 5).

If the output state is a superposition state, the situation is a bit more complicated. For a single quantum computer subject to a “hard” measurement (assumed in Section 2.2), the superposition “collapses” to one of the terms in the superposition, with probabilities given by the square of the amplitude of each term. In contrast, NMR spectra result from averaging over a large number of independently operating quantum computers (molecules), and for each spin the area under the spectral lines is proportional to the $|0\rangle - |1\rangle$ probability difference.

The output state of equation (6) serves as an example: half of the molecules in the ensemble collapse to $|0\rangle$ ($|000\rangle$), while the other half collapses to $|4\rangle$ ($|100\rangle$). In other words, spins 2 and 3 always end up in “0” so their spectral lines are absorptive; in contrast, the signal of spin 1 averages to zero because there are equally many molecules in which spin 1 ends up in “0” as in “1”. It is not clear that such bit-wise averages of probabilistic output states are generally sufficient to solve the problem of interest. For Shor’s period-finding algorithm, this problem can be circumvented⁸ by performing the classical post-processing steps (Section 2.3) on the quantum computer using ancillae qubits; any classical computation can also be done on a quantum computer.⁵ In this way, the output state becomes the period r for all the molecules in the ensemble (as opposed to an average over all the multiples of N/r) and the measurement result becomes deterministic.

Instead of recording the signal of each of the output spins, it is sometimes possible to use the extra information provided by the line splittings due to J couplings to derive the output state of several qubits from the spectrum of a single spin. Since each of the lines in the multiplet can be identified with specific states of the other spins (as in Figure 4), the presence or absence of each line in the multiplet gives information about the state of the other spins (Figure 5).

Finally, while the spectra of a few select spins suffice to obtain the answer to a computation, the full density matrix

Figure 5 Output spectra of the proton (a) and carbon (b) spins of $^{13}\text{CHCl}_3$ (dissolved in a liquid crystal solution) for four different executions of Grover's search algorithm. Only the real part of the spectra is shown, and frequencies are relative to ν_H and ν_C . A positive or negative line in the spectrum indicates that the corresponding spin was in $|0\rangle$ or $|1\rangle$ before the read-out pulse. Furthermore, the position of the line in the spectrum of one spin also reveals the state of the other spin. For example, if the ^1H line is at $\nu_H - J_{\text{CH}}/2$, the ^{13}C spin is in $|0\rangle$; a ^1H line at $\nu_H + J_{\text{CH}}/2$ indicates the ^{13}C spin is in $|1\rangle$. Thus, the state of the two qubits for each of the four cases is (from top to bottom) $|00\rangle$, $|01\rangle$, $|10\rangle$ and $|11\rangle$. (Reproduced from Ref.⁶¹ by permission of the American Institute of Physics)

conveys much more information. This extra information can be used to expose the presence of errors such as multiple quantum coherences not visible in the single output spectra and furthermore is a useful tool for debugging pulse sequences. The procedure for reconstructing the density matrix is called quantum state tomography.^{43–45} It consists of repeating the computation multiple times, each time looking at the final state of the spins after applying different sets of read-out pulses which rotate different elements of the density matrix to observable positions. However, since this procedure involves on the order of 4^n experiments, it is practical only for experiments involving a few spins.

3.5 State of the art and Outlook

To date, only very simple demonstrations of quantum algorithms, all using liquid-state NMR techniques, have been carried out. Variations of Grover's algorithm have been demonstrated with two^{44,49,50} and three qubits,³⁶ the Deutsch–Jozsa algorithm with two,^{43,51} three⁵² and five⁵³ qubits, and the

period-finding algorithm with five qubits.²⁶ Most recently, a seven-qubit quantum computer has been used to factor the number 15 using Shor's algorithm.⁶⁷ A quantum simulation has been implemented with two⁵⁴ and three⁵⁵ qubits, and quantum error detection and correction with two,⁵⁶ three⁵⁷ and five⁶⁸ qubits. Finally, a 7-spin coherence has been created and observed²⁵ (see Ref.⁶ for additional references). While these experiments indeed demonstrate the principles of quantum information processing, they all involve far fewer qubits than would be needed to solve a problem beyond the reach of classical machines.

Despite the rapid progress in recent years, scaling liquid state NMRQC to tens or hundreds of qubits may be impractical for several reasons, although none of them appear fundamental. In particular, as the number of qubits increases: (1) the strength of the signal selected with current state initialization techniques decreases exponentially,^{8,9,58} but Schulman–Vazirani cooling⁴¹ does not suffer any such exponential overhead (Section 3.2); (2) the chemical shift separations unavoidably become smaller,

but Lloyd³² showed that for universal quantum computation it suffices to have a linear chain $d - abc - abc - \dots - abc$, in which only nearest neighbour spins are coupled and with only four distinct chemical shifts δ_a , δ_b , δ_c and δ_d ; (3) J -couplings become smaller or even unresolved, but this can be circumvented by swapping spin states (Section 3.2).³² While these obstacles are not fundamental, the solutions all make the pulse sequences, very likely impractically, much longer. This would require increasingly longer T_2 and T_1 for larger molecules, while in practice the T_2 and T_1 tend to become shorter (see **Relaxation: An Introduction**, Volume 6).

NMRQC has also brought up new theoretical issues: (1) since only ensemble averaged results are available because of the large number of molecules in a sample tube, some information is lost that would be available in an idealized quantum computer such as a single molecule at zero degrees Kelvin. For the known quantum algorithms, this information can be retrieved by performing classical post-processing steps on the quantum computer (Section 2.3); and (2) since the density matrix of nuclear spins at room temperature is very close to the identity matrix, it is not possible to produce genuinely entangled states between the nuclear spins in small thermally polarized molecules in liquid solution.⁵⁹ This observation has sparked a stimulating debate about the “quantumness” of NMR, because it implies that each of the states produced in NMRQC experiments so far is classical. However, all attempts to describe the dynamics of a set of coupled spins by an efficient classical model have been unsuccessful. It is thus conjectured that even though the states show no entanglement, the dynamics of the spins is truly quantum mechanical,⁶⁰ a proposition which will appear obvious to most NMR spectroscopists. In fact, it has also been the starting point of this introduction to NMR quantum computing.

4 SUMMARY AND CONCLUSIONS

In many respects, liquid state NMR provides an ideal test bed for elementary quantum computations. The degree of control over the evolution of multiple coupled qubits – the result of 50 years of technology development – the long relaxation times of nuclear spins and a set of new insights^{8,9} made it possible to perform certain computations in *fewer steps* than is possible using any classical machine. This is in itself a remarkable achievement.

It is unlikely that liquid state NMR could ever be used to solve problems *faster* than any classical machine, but it has already inspired many other NMR based proposals for quantum computing. Liquid-crystal solvents have been used to partly reintroduce dipole-dipole couplings (see **Liquid Crystals: General Considerations**, Volume 4) to speed up the gate time and increase the number of gates possible within the coherence time.⁶¹ New molecular architectures based on liquid crystal solutions are now being investigated. Solid-state NMR near 0 K could circumvent the state initialization problem, but also poses new questions in terms of addressability and coherence times (see **Internal Spin Interactions & Rotations in Solids**, Volume 4). Several approaches to solve these issues have been proposed.^{62,63} Another proposal which received much attention consists of doing NMR on impurity atoms placed in a linear or two-dimensional array, with chemical

shifts and couplings controlled by electrodes placed on top of and in between the impurity atoms.⁶⁴

Furthermore, there is a plethora of very different experimental approaches to building quantum computers (for an extensive review, see Ref.⁶⁵). Four trapped ions have recently been entangled⁶⁶ and a single quantum logic gate has been implemented between two photons coupled with each other via interactions with an atom in a cavity.⁶⁹ In the long run, the most scalable approaches may be those based on solid-state technology, such as electron spins in quantum dots or magnetic fluxes in SQUIDS.⁶⁵

It is clear that none of these proposals will be easy to implement since they all require substantial and innovative development of technology. The success of any approach will depend on the ratio of the coherence time to the gate duration, i.e., how many gates can be completed within the coherence time, and on the achievable degree of quantum control.

Many of the problems in quantum control are similar for different experimental systems, and we therefore expect that other quantum computer implementations will benefit from the ideas, concepts and solutions which arise from liquid state NMR experiments. In addition, we hope that some of the techniques developed within the context of quantum computation may find more general application in NMR.

The possible payoff for successful quantum computing is tremendous: to solve problems beyond the reach of any classical computer. It is not clear at this point whether quantum computers will fulfill this promise, but in any case quantum computing has already provided an exciting new perspective on NMR and, more broadly, on the connection between physics, information and computation.

1 INTRODUCTION

By the late 1950s, all of the physics important to high-resolution solution NMR seemed to have been identified. The basic interactions of chemical shift and scalar or J couplings, as well as the dynamics leading to spin relaxation and chemical exchange, were understood—at least in principle. It seemed that all of the relevant terms in the Hamiltonian that applied to NMR in isotropic solutions were known. Advances in NMR theory focused on the details of dealing with complex spin systems and their manipulation by pulse trains, or how the spins reflected molecular dynamics, as exemplified in this Encyclopedia. This article deals with the recent recognition of an additional term in the solution NMR Hamiltonian, namely, that for nuclear–nuclear exchange coupling, and the dramatic effects it can have on solution NMR spectra. The purpose is to provide the reader with as intuitive and physical a picture of this purely quantum mechanical effect as possible. More rigorous treatments of the details of the underlying physics may be found in the references.

2 EXPERIMENTAL OBSERVATIONS

The discovery of nuclear–nuclear exchange couplings or quantum exchange couplings in solution NMR spectroscopy^{1–3} grew out of NMR studies of transition metal polyhydrides in the 1980s. Kubas at Los Alamos National Laboratory had discovered a class of transition metal complexes that bind H_2 as an intact ligand, rather than oxidatively adding the H_2 to the metal center.⁴ This prompted a great deal of activity among inorganic chemists in the synthesis of new hydride and dihydrogen complexes, as well as the reinvestigation of many previously known systems. At the time, the synthetic chemists also postulated that species such as H_3^+ might also be stabilized as ligands in transition metal complexes. Solution NMR spectroscopy of 1H was usually the structural method of choice in these investigations, and the classic signature of an H_2 complex became a measurable value for $^1J(^1H, ^2D)$ in the HD isotopomer, usually of the order of 20–35 Hz. It was widely assumed that a large value of $^1J(^1H, ^1H)$ would be found in any H_3 complex.

In the late 1980s, Heinekey at Yale and Chaudret at Toulouse independently^{5,6} made some somewhat startling observations

in the 1H NMR of several transition metal trihydrides. In these systems, the spectra indicated that $^1J(^1H, ^1H)$ could be over 200 Hz. Since the coupling in molecular H_2 itself is only 280 Hz as inferred from the NMR of HD, these large values for 1J were at first glance evidence for the putative H_3^+ complexes. However, it soon became clear that these systems were not to be explained so simply. During the next few years, Heinekey carried out a set of classic experiments that formed the basis on which it is now accepted that these splittings are exchange couplings.

One of the first indications that the observed splittings were not due to the usual Fermi-contact mediated scalar coupling mechanism was their extreme sensitivity to temperature. Early on, the apparent J couplings seemed to be field-dependent. However, careful experiments by Heinekey showed that this apparent B_0 dependence arose from slight variations in the probe temperature on different instruments. The splittings in fact did not depend upon field, but instead were hypersensitive to temperature. Many alternate models were considered for explaining these observations at the time. Some invoked chemical equilibria involving an unusual thermally accessible state that would have unprecedentedly large J couplings. Several tunneling-type mechanisms were also considered, but these seemed difficult to resolve with the observation of these splittings in fluid media at close to ambient temperatures. (For a review of previous experimental observations, other models eliminated, and pertinent references, see Zilm and Miller.⁷) Heinekey then carried out some very important experiments employing 2D substitution. The resulting pattern of isotope shifts and the isotopic variations on the apparent values of $^1J(^1H, ^1H)$ in the remaining protons ruled out any sensible model involving chemical equilibrium.² Unfortunately, the spectra of the partially deuterated isotopomers themselves did not provide convincing evidence for the involvement of tunneling. While no $^1J(^1H, ^2D)$ couplings were observed, this observation could be explained just as convincingly by self-decoupling due to the rapid 2D relaxation in concert with chemical exchange as by a tunneling mechanism. The key experiment to perform became clear. The NMR of a partially tritiated isotopomer would have none of the complications encountered with deuterium. Given the difficulties in handling radioactive samples, this experiment was more than difficult to perform. The results were well worth Heinekey's efforts: a coupling that started as over 500 Hz in a perprotio molecule was reduced to a $^1J(^1H, ^3T)$ of less than 30 Hz at the same temperature.¹ This was the first conclusive evidence obtained in favor of the exchange coupling mechanism for these large temperature dependent couplings. The initial report¹ of this result and a theoretical framework for quantitatively accounting for these couplings and their temperature dependence was soon published. Simultaneously with this report, Jones and Weitekamp⁸ also proposed an exchange coupling mechanism in these systems, which utilized symmetry arguments, but with no additional experimental data.

3 THEORY

Exchange interactions among electrons are familiar to any student of solid state physics or quantum chemistry. They are central to the quantum mechanical description of bonding in

molecules and the mechanism of phenomena such as high-temperature superconductivity. The appearance of $J\mathbf{I}_1 \cdot \mathbf{I}_2$ type couplings in ESR spectra of triplet biradicals is a well-known spectroscopic manifestation of the electron–electron exchange interaction. For nuclei, quantum mechanical exchange interactions are less familiar, and until recently they were not known to affect high-resolution magnetic resonance spectra in any manner. (For references on quantum exchange in solid ^3He and in related electronic structure problems, see Zilm and Miller.⁷) The best-known example of heavy particle quantum exchange is in solid ^3He . In this system, diffusion rates and other properties are known in large part to be determined by ^3He – ^3He exchange interactions. NMR spectra of tunneling methyl groups at low temperature also display features related to rotational tunnel splittings, but these have not usually been considered as manifestations of an exchange interaction per se. Given that quantum effects such as these have typically been considered as purely low-temperature phenomena, it is not surprising that quantum exchange involving nuclei has not until recently been recognized as having any role in solution NMR spectroscopy.

Any theory accounting for quantum exchange must consider the total wavefunctions for the nuclei being observed, spanning both spin and spatial coordinates. In this respect, quantum exchange is quite distinct from the other terms in the NMR Hamiltonian. A typical NMR interaction can usually be written as a product of a spin operator and an interaction constant or tensor, which is an expectation value of the rest of the system Hamiltonian over all coordinates except spin. In quantum exchange, however, the spin coordinate and the spatial coordinate are correlated, and such a separation is not possible. To illustrate this, we shall consider a simple two-spin system where the spins occupy chemically inequivalent sites.

3.1 Molecular Dynamics

To understand quantum exchange in the context of NMR spectroscopy, we must first consider the quantum mechanics governing the Cartesian displacements of the NMR active nuclei, i.e., their orbital wavefunctions, and then see how this is coupled to their spin coordinates, i.e., the spin functions. For a start, we shall consider a simple two-particle quantum mechanics problem that is often somewhat misunderstood. Although our treatment will be quite similar to a number of familiar problems in tunneling (see, e.g., Atkins⁹), we should like to emphasize now that quantum exchange does not in fact imply that tunneling motions occur. This point will be clarified in the following discussion.

The molecular systems in which quantum exchange has been observed by NMR all are of the form (1)

where the other ligands collectively denoted by L_3 are typically another hydride, a cyclopentadienyl, and a phosphine. Single crystal neutron diffraction studies³ indicate that the hydrides are typical terminal hydrides having a single bond to the central transition metal atom M. Although the M–H linkages are

significantly more ‘floppy’ than C–H bonds, these hydrides are basically localized at their binding sites. To a very good approximation, the potential well that each of these hydrides experiences can be approximated by the harmonic oscillator potential as depicted in Figure 1(a).

A complete quantum mechanical treatment of the pair of hydrides under consideration would involve a six-dimensional potential energy surface describing the energy of all configurations of the two hydrides as they are moved relative to each other and to the metal center. As long as the hydrides remain outside each other’s van der Waals radii, the potential experienced by either is still roughly harmonic. If the hydrides do not have any appreciable interaction with one another, the problem reduces to that of two uncoupled harmonic oscillators.⁷

As a simple model for this system, consider two hydrides bound to a surface, each in locally harmonic single particle potentials, (2) and (3).

If the interaction between the two protons is sufficiently weak, their displacements are approximately harmonic except for the symmetric displacement towards one another. In this instance, each hydride feels a repulsive force, which rises rapidly as they near one another. The hydrides are also attracted to the potential minimum at the other binding site. It is the displacement of the hydrides along this type of coordinate that we shall focus upon.

A good model potential for displacements along this exchange coordinate is a double well potential such as that in Figure 1(b). Movement along this coordinate exchanges the two hydrides between the two wells. The reaction coordinate is a two-particle potential, and is necessarily somewhat complicated. If the hydrides simply each moved along the y axis towards one another, there would be an essentially infinite barrier separating the two configurations. The model we want to consider instead takes the coordinate to be a minimum energy type of path along which exchange is possible. At the barrier the two particles must move out of each other’s way along a path that takes them out of the (y, z) plane.

It is worthwhile to note what is, and what is not, important in the choice of this potential energy curve. The double well model is only one approach to connecting the two different possible ground state configurations of the hydrides. Displacement on a periodic rotational coordinate would also produce the type of effects to be discussed.¹⁰ The required features are only that the potential has two wells representing two distinct configurations and that there be a finite barrier separating them.

Having reduced the two-particle problem to a single internal reaction coordinate in a double well makes the problem fairly simple. We shall only consider the vibrational ground state in this potential, since we know that the hydrides are basically bound fairly tightly to their binding sites. This places them in one of the two configurations representing the double well minima. Near the bottom of either well, the potential is close to harmonic, and a good approximate two-particle ground state

Figure 1 (a) Depiction of two harmonic potentials at two different sites, with vibrational ground state wavefunctions. This is a reasonable description of two largely uncoupled M–H vibrators in a transition metal hydride. The coordinates are the displacements of the individual hydrides. (b) A model two-particle potential describing the change in potential energy as the two hydrides in the two sites shown in (a) are exchanged between the two sites. The coordinate is the reaction coordinate along which the exchange takes place. The wavefunctions shown are two-particle wavefunctions for the two degenerate configurations

wavefunction would be a Gaussian centered in either of the two wells. We define $\psi(L)$ as the configuration where the protons 1 and 2 were at sites A and B, respectively. This configuration can be written as a product of one-particle wavefunctions, i.e., $A(1)B(2)$, where $A(1)$ and $B(2)$ are the Gaussians representing the one-particle ground state vibrational wavefunctions in the single particle potentials representing the two binding sites. The other side of the double well would then be represented by the two-particle wavefunction $\psi(R)=A(2)B(1)$ [see Figure 1(b)].

It is tempting to apply what we know about the quantum mechanics of a single particle in a double well directly to this two-particle problem, since the mathematical formulation is now the same at this point (see, e.g., Atkins⁹). Because the wells are a finite distance apart, the wavefunctions for the two ground state basis configurations we have chosen overlap each well. This produces an off-diagonal element in the matrix for the system Hamiltonian $\hat{\mathcal{H}}_L$ that includes the interaction of the particles with both wells and each other. To get the best possible description of the ground state within this restricted basis set, we must diagonalize this matrix. If

Figure 2 Model double well exchange potential showing the two lowest energy eigenfunctions ψ_+ and ψ_- . The energies of these two states are split by $2J$ symmetrically about the energy of the two degenerate localized basis states

the two sides of the double well have the same depth, the basis states are degenerate. No matter how small the off-diagonal term, the two basis set wavefunctions will be mixed. As every student of quantum mechanics knows, in the single particle case the symmetric and antisymmetric combinations of the two Gaussians are then good approximations to the proper wavefunctions. The eigenenergies of the two eigenstates $\psi_{\pm} = \frac{1}{2}[\psi(L) \pm \psi(R)]$ for the symmetrical potential are $E_{\pm} = \bar{E} \pm J$ (see Figure 2). $\bar{E}$ is the unperturbed energy of either of the degenerate configurations given by

$$\int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \quad (1)$$

and J is the value of the off-diagonal matrix element

$$\int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \quad (2)$$

In the case of a single particle in the double well, the energy difference $2J$ is a tunnel splitting. The wavefunctions indicate that the particle is equally likely to be in either well. This is interpreted to mean that the particle is ‘delocalized’ over both sides of the potential. If a localized state is prepared by a superposition of ψ_+ and ψ_- , it will evolve in time according to the usual rules of time-dependent quantum mechanics. The picture that emerges is one of the maximum in the probability density oscillating between the two wells at a frequency $2J/\hbar$. One usually describes the particle as coherently tunneling from one well to the other at this rate. On the other hand, when the two wells are of differing depths, the particle quickly becomes localized. As long as the difference in the energies of the two states $\psi(L)$ and $\psi(R)$ is larger than the off-diagonal term J , these remain good states to first order in the perturbation treatment.

The mapping of the two-particle case onto this reduced one-particle description contains some subtleties. If the two

sites are energetically the same, i.e. the one-particle potentials at the two binding sites are identical, the configurations $A(1)B(2)$ and $A(2)B(1)$ will clearly have the same energies. The degeneracy will again be lifted by any finite matrix element connecting the functions $A(1)B(2)$ and $A(2)B(1)$, and there will be two states separated by a tunnel splitting. In the molecules we are considering, however, the hydrides are chemically inequivalent. This means that the local one-particle potentials are different, if only slightly so on a cm^{-1} scale. However, this does not necessarily break the symmetry of the two-particle potential along the exchange coordinate. If the two particles are identical, the basis configurations $A(1)B(2)$ and $A(2)B(1)$ representing $\psi(L)$ and $\psi(R)$ will still have the same energies. Exchange of identical particles can then be described by a mirror-symmetric two-particle potential in the exchange coordinate. If the hydrides are not identical (e.g., a proton and a triton), this symmetry will be broken, since the two basis configurations will have different energies. The eigenstates will then be localized, and no tunneling will occur. In this case of two distinguishable particles, the two sites would have to be identical for the exchange potential to remain symmetric.

The appearance of a potential for particle exchange with mirror symmetry is then a prerequisite for exchange splittings to appear in the energy level diagram for this two-particle system. Many familiar systems have this type of symmetry, but not all can display quantum exchange. For example, consider the umbrella mode of ammonia, or the chair-to-chair inversion of cyclohexane. In the gas phase, both displacements can be described by mirror-symmetric double wells. Placing these molecules into a condensed phase, however, breaks this symmetry. When either molecule inverts, it moves from one region of space to another. The presence of an anisotropic solvent shell around each site gives the configurations distinct energies. This is not the case for the transition metal polyhydrides we are considering, or other systems such as rotating methyl groups. In the transition metal hydrides, the configuration before and after the exchange of two hydrides occupies the same region of space. Rotation of a methyl group by 120° likewise results in a new configuration that occupies the same space as before the rotation. These displacements are then always instantaneously described by mirror-symmetric potentials, and thus will have exchange-type splittings appearing in their energy level structure. It should be emphasized that whether particles are identical or not depends only on the nature of the particles and not on their location in the molecule or lattice. However, whether a molecular rearrangement that exchanges identical particles is a truly degenerate rearrangement energetically depends on the relation of the molecule to the lattice at the beginning and the end of the rearrangement.

The above treatment of the two-particle exchange problem as a single pseudoparticle in a double well is only partially correct. This is because the two-particle wavefunctions have additional constraints. One must remember that the spatial portion of a wavefunction describes the probability of a particle's location. When several particles are described by a single wavefunction, the probabilities can only be ascribed individually to particles that are distinguishable. For indistinguishable particles, the identity (e.g., particle number) is irrelevant.¹¹ The wavefunction for a pair of identical particles can then only give the probability of finding a particle

of that type at any position. It cannot tell us the probability for finding a particular particle there.

Our interpretation of $\psi_{\pm}$ in the one- and two-particle cases, then, is somewhat different. For the single particle in the double well, the equal probability amplitudes on the left and right sides is taken as an indication that the particle is 'delocalized' over both sides. This notion is reinforced by the time-dependent behavior of a single particle in this potential if the initial state is localized as just discussed. On the other hand, the two-particle wavefunctions $\psi_{\pm}$ do not imply delocalization of the two particles, or of the configuration. These functions now simply state that the system is most likely in a configuration with one particle on the left and one on the right, but the identity of the configuration is indeterminate. We may not ask about the location of individual particles, since they are identical, and as such their labels are simply irrelevant. Thus, we see in the two-particle case that the indeterminacy as to which particle is on the left or on the right has replaced the delocalization that arises in the one-particle problem.

This statistical interpretation of the two-particle wavefunctions requires that any relabeling of the particle identities must leave the probability densities unchanged. Thus, the wavefunction must be the same, or at most change sign, when the particle labels are permuted. In accord with the well-known symmetrization postulate, wavefunctions for identical bosons are symmetric or remain the same, while those for identical fermions are antisymmetric or change sign, under particle label exchange. With this in mind, we return to the problem of two particles in the double well. Consider the case where the particles are of zero spin and are therefore bosons. The function ψ_+ has the proper symmetry, while ψ_- does not. The ground state can then only exist as ψ_+ , since ψ_- is an unacceptable wavefunction. The consequence of this is that a 'localized' state cannot be constructed by combining ψ_+ and ψ_- . The picture we arrived at in the one-particle state of an initially localized state periodically moving between the two wells is then inappropriate. The system can only remain in the ground state ψ_+ . This is most easily interpreted as the system being localized in one of the two possible indistinguishable configurations.

3.2 Including the Spin Coordinate

When the spin functions are included in the two-particle problem, the symmetry of the total wavefunction including spin must be considered. One place to start is to write the individual spatial and spin functions as separate symmetrized sets. For a pair of spin- $\frac{1}{2}$ nuclei the symmetrized functions are the symmetric triplet functions T_0 , T_{-1} , T_{+1} , and the antisymmetric singlet spin function S_0 . The total wavefunction for identical fermions must be antisymmetric with respect to exchange, and therefore ψ_+S_0 , ψ_-T_0 , ψ_-T_{-1} , and ψ_-T_{+1} are the only acceptable combinations. Now that spin has been introduced, the system can have an energy of either $E + J$ or $E - J$, depending upon the spin state of the nuclei. Any additional small interaction of the magnetic field would not be expected to change the situation with respect to the energy associated with the orbital or lattice terms of the Hamiltonian. On the other hand, magnetic interactions will mix the singlet and triplet spin manifolds. Any spin flip that occurs must also make up any difference in lattice energy accompanying the transition. The appearance of the exchange energy in an

NMR transition is then a consequence of the correlation of the spin states with the orbital energies associated with the displacements of the NMR active nuclei.

In general, the above type of prescription for determining properly symmetrized total spin + spatial wavefunctions is cumbersome. The resulting functions can be recast in a more physical and convenient basis, which we call the site spin basis.¹¹ Rather than deriving the site spin basis, we shall develop it directly from some basic symmetry considerations. Let us start by considering a pair of protons in chemically equivalent sites that comprise an AX spin system. Normally we ignore the complications brought on by the coordinate or orbital part of the wavefunction, and simply write the spin eigenfunctions as $|+ +\rangle$, $|+ -\rangle$, $|- +\rangle$, and $|- -\rangle$, where the labels refer to m_S for particles 1 and 2 in that order. These two-particle product basis spin functions themselves, however, do not have the proper symmetry with respect to particle exchange, i.e., $|+ -\rangle \neq \pm |- +\rangle$. This at first sight seems perplexing, since every NMR spectroscopist knows that these wavefunctions are what are always used for an AX spin system. The answer is that in actuality the spin labels do not refer to the particle identities. Instead, the functions are of the form $|m_S(A), m_S(B)\rangle$, i.e., the labels are according to the site identity, not the particle numbers. The function $|+ -\rangle$ says the particle in site A is in the + state, and the particle in site B is in the - state. What the function does not tell us is which particle is in which site. Therefore, the spin functions labeled according to the m_S in each site are automatically symmetric with respect to particle exchange. To differentiate the product basis labeled according to sites, we shall write these kets as $|+ -'\rangle$.

In using this site labeling convention, we must also relabel our spin Hamiltonian.¹¹ For instance, the Zeeman plus chemical shift term in frequency units for two spins would be written as

$$\hat{\mathcal{H}}_{cs} = -\nu_A \hat{I}_{zA} - \nu_B \hat{I}_{zB} \quad (3)$$

The resonance frequencies and spin operators are thus identified with the molecular site instead of a particle number. In most instances, this is in fact how NMR problems are typically handled, even though one may have the impression that one is using particle labels instead of site labels.

The overall symmetry of the total site spin basis function $\psi_{\text{site}} = \psi_{\text{orbital}} \psi_{\text{spin}}$ is then determined solely by the symmetry of the orbital wavefunction. For this pair of spin- $\frac{1}{2}$ nuclei, ψ_{orbital} must always be the antisymmetric function ψ_- , since ψ_{spin} is always symmetric with this site labeling convention. The total wavefunction for the $|+ -'\rangle$ spin state is then $\frac{1}{\sqrt{2}}[A(1)B(2) - A(2)B(1)]|+ -'\rangle$ (the normalization is only approximate, since we have ignored the small overlap term). As a shorthand, these site spin basis functions will be written as $|m_S(A), m_S(B)\rangle$, dropping the prime notation to imply the inclusion of the orbital portion. Remember that the labeling of the spin portion is according to site A and B, not particle 1 and 2, in these functions with the $[\]$ notation. In order to calculate a spectrum, it is instructive first to explicitly calculate a few matrix elements. We shall use the sum of the coordinate Hamiltonian for the particles, $\hat{\mathcal{H}}_L$, and $\hat{\mathcal{H}}_{cs}$ as an example.

First consider $\langle + - | \hat{\mathcal{H}}_{cs} | + - \rangle$. Using the site labeling convention, this is evaluated as $\frac{1}{2}(\nu_B - \nu_A)$ in the usual fashion. The integral over the particle coordinates is unity, since the

orbital function is normalized. To calculate $\langle - | \hat{\mathcal{H}}_L | + - \rangle$, we must expand $|+ -\rangle$ in terms of functions with particle labels:

$$|+ -\rangle = \frac{1}{2}[A(1)B(2)|+ -\rangle - A(2)B(1)|+ -\rangle] \quad (4)$$

Since the spins have particle number designations on the right-hand side, the + and - labels have been arranged to keep the + spin in the A site and the - spin in the B site. The quantity $\langle + - | \hat{\mathcal{H}}_L | + - \rangle$ can be written as a sum of products of integrals over spin and space separately:

$$\begin{aligned} \langle + - | \hat{\mathcal{H}}_L | + - \rangle &= \frac{1}{2} \langle + - | + - \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad + \frac{1}{2} \langle - + | - + \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle - + | + - \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle + - | - + \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \end{aligned} \quad (5)$$

Note again that the spin labels on the left refer to sites A and B, while those on the right refer to particle numbers 1 and 2. The first two integrals each give $\frac{1}{2}E$, and the last two are zero because of the vanishing integral over the spin coordinate. The net value of the element $\langle + - | \hat{\mathcal{H}}_L | + - \rangle$ is then the lattice energy E . Now consider the element $\langle - + | \hat{\mathcal{H}}_L | + - \rangle$. In a similar fashion, the integral can be expanded as

$$\begin{aligned} \langle - + | \hat{\mathcal{H}}_L | + - \rangle &= \frac{1}{2} \langle - + | + - \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad + \frac{1}{2} \langle + - | - + \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle + - | + - \rangle \int \int [A(2)B(1)]^* \hat{\mathcal{H}}_L A(1)B(2) d\tau_1 d\tau_2 \\ &\quad - \frac{1}{2} \langle - + | - + \rangle \int \int [A(1)B(2)]^* \hat{\mathcal{H}}_L A(2)B(1) d\tau_1 d\tau_2 \end{aligned} \quad (6)$$

In this case, the first two integrals are zero, and the second pair give contributions of $-\frac{1}{2}J$ for a total value of $-J$.

The reader may already see that these matrix elements can be evaluated on inspection following a few simple rules. When dealing with the NMR or spin Hamiltonian, we proceed as normally, using spin operators, interaction coefficients, and spin functions labeled according to site. The coordinate part seems trickier, but can be simply treated as a permutation operator over the spin. For a term $\langle ij | \hat{\mathcal{H}}_L | kl \rangle$, a value of E is returned if $i = k$ and $j = l$. If $i = l$ and $j = k$, a contribution of $-J$ is obtained. The additional terms that the exchange interaction brings to the NMR Hamiltonian can then be recognized as having the same form as the classical exchange matrix familiar to students of dynamic NMR lineshape analysis.

Table 1 Hamiltonian Matrix in the Site Spin Basis for a Simple AX Spin System

	$ + +\rangle$	$ + -\rangle$	$ - +\rangle$	$ - -\rangle$
$\langle ++ $	$-\frac{1}{2}\nu_A - \frac{1}{2}\nu_B + E - J$	0	0	0
$\langle +- $	0	$-\frac{1}{2}\nu_A + \frac{1}{2}\nu_B + E$	$-J$	0
$\langle -+ $	0	$-J$	$+\frac{1}{2}\nu_A - \frac{1}{2}\nu_B + E$	0
$\langle -- $	0	0	0	$+\frac{1}{2}\nu_A + \frac{1}{2}\nu_B + E - J$

For our simple AX spin system, the full Hamiltonian matrix in the site spin basis can then be written on inspection as in Table 1. Since the orbital energy E only adds to the diagonal, it just represents a shift of the energy scale and can arbitrarily be set to zero. If the chemical shift difference $|\nu_A - \nu_B| \gg |J|$ then the off-diagonal terms will be truncated, and the NMR transitions will give two doublets centered at ν_A and ν_B with splittings of $-2J$. This Hamiltonian then gives the same spectrum as that for an AX spin system with an effective J coupling of $-2J$. Since the matrix element that J represents is inherently negative, the apparent coupling in the spectrum is positive. For spin- $\frac{1}{2}$ nuclei, it can be shown that any pairwise exchange interaction gives rise to a term that behaves just as if there were a scalar coupling $-2J$ between those two sites. Higher-spin systems, however, cannot be described by such a simple effective spin Hamiltonian.¹¹

One could incorrectly infer from the energy level structure of this simple example that the identity of the particles can somehow be made known by the fact that they experience different chemical shifts at the two different sites. A question that might be asked is how often the spins can change places by tunneling. The answer turns out to be that one cannot tell. The probability that a spin in site A has exchanged with a spin in site B becomes a maximum when their spin quantum numbers are identical. In other words, the spins can tunnel when one cannot tell them apart, even by their spin. Therefore, the most straightforward interpretation is that the spins remain localized, but which spin is localized where is something that cannot be known, since the particles are indistinguishable.

The advantage of the site spin basis approach to treating exchange coupling in NMR spectroscopy is that it is very easily extended to more complicated permutations or exchanges of spins, and is easily applied to problems involving nuclei of arbitrarily large I . The general form of the exchange Hamiltonian in the site spin basis can be shown¹¹ to be

$$\hat{H}_{\text{ex}} = \sum_i \xi^{p(i)} J_i \hat{P}_i(k, l, m, \dots) \quad (7)$$

where $\xi = e^{2\pi i l}$ and I is the spin quantum number of the nucleus in question. The permutation of the spins among the sites $k, l, m, \dots$ is represented by the operator $\hat{P}_i(k, l, m, \dots)$, which acts on the spin labels within the site spin basis functions. Each site spin basis function has the same orbital function implied. For fermions, this is formed using a Slater determinant for the orbital states for each site. If the nuclei are bosons, an antideterminant is used instead. The exchange matrix element is given by J_i . It is calculated by taking the matrix element of $\hat{H}_L$ between an orbital state for one configuration and that of the configuration resulting from the permutation. For example, consider a three-site problem (e.g., a methyl group). A starting configuration would be

$A(1)B(2)C(3)$. If the three particles are subjected to a cyclic permutation, this state would become $A(3)B(1)C(2)$. The value of J_c would be

$$J_c = \iiint [A(1)B(2)C(3)]^* \hat{H}_L A(3)B(1)C(2) d\tau_1 d\tau_2 d\tau_3 \quad (8)$$

Different permutations have different parities. For bosons, this is irrelevant. However, for fermions, permutations of even parity produce negative elements, and those of odd parity give positive exchange integrals. This is handled by the $\xi^{p(i)}$ term. If the nuclei are fermions with spin $I = n + \frac{1}{2}$ then $\xi = -1$. If they are bosons then $\xi = +1$. For fermions, a single pairwise permutation has odd parity, and $p(i) = 1$, which produces a negative sign for the exchange matrix element. On the other hand, a permutation that can be written as the product of two pairwise permutations has even parity, and $p(i) = 2$. These permutations give positive exchange coupling elements in the Hamiltonian matrix. One can show by straightforward but tedious calculations that the results of this prescription are to reproduce the matrix elements that would be obtained by expanding the site spin basis functions as products of properly symmetrized orbital functions and spin functions with particle labels, and performing the integration explicitly.

In practice, one simply associates a different J value with each particular topological rearrangement or permutation of the nuclei between the different locations in a molecule. High barrier permutations give low J values, and facile permutations give larger ones. The states that are connected are those where the permutation operation shuffles the spin labels so that they match those of the state to which it is coupled. The procedure is exactly the same as filling an exchange matrix for a classical chemical exchange lineshape problem. The signs of the elements are determined by whether the spins are fermions or bosons, and whether the permutation has even or odd parity. These elements are added to the rest of the standard NMR Hamiltonian, and the spectrum is determined by finding the eigenstates and determining the transition moments in the usual fashion.

A convenient starting point for computer simulation of exchange-coupled spectra in the presence of chemical exchange is to start with any of the many programs for dynamic NMR lineshape simulation. One simply duplicates the code for calculating the elements of the classical exchange matrix, and uses it to add exchange coupling elements to the Hamiltonian matrix. In this manner, we have been able to computer-simulate exchange-coupled NMR spectra for systems of up to four chemically exchanging protons or deuterons.

3.3 Temperature Dependence

Our main purpose so far has been to provide a physical picture of how exchange interactions produce splittings in

NMR spectra. The theory accounts for the disappearance of exchange couplings between different isotopes of the same element, for the persistence at ambient temperatures of an effect that is similar to tunneling, and for the different spectral patterns that are observed for spin- $\frac{1}{2}$ and spin-1 systems (see below). Accounting for the size of these splittings and their temperature dependence is another matter. Several models have been proposed, and probably all are correct to some extent. A definitive calculation of the exchange coupling would require an accurate $3N$ -dimensional potential energy surface for N identical nuclei. This is at present out of reach, so the models are either approximate analytical or computational attempts to focus on key features of the exchange process.

The model we have favored most is based on a treatment of exchange in solid ^3He by Landesmann.^{2,7} Landesmann has analytically calculated the ground state exchange splitting for two atoms in harmonic wells and repelled by a hard sphere potential. To account for the temperature dependence, thermal excitations that place the molecules in higher vibrational states are involved. Since these vibrationally excited states are more delocalized, there is more overlap of the individual particles with the neighboring sites, and the size of J goes up with vibrational quantum number. In the double well description, the splittings of the higher states increase exponentially as one moves beyond the ground state. In solution, the vibrational states are short-lived, and the NMR experiment measures a Boltzmann population weighted average of the splittings over the vibrational ladder. The spin state is conserved in these transitions, and the sign of J remains the same; therefore, the weighted average of J increases with temperature. We have shown that the sum over vibrational states can be effectively accomplished by first calculating a Boltzmann population weighted overlap function.⁷ This can be shown to be approximated by a Gaussian of increasing width with increasing temperature. As Landesmann's ground state calculation used a Gaussian basis set, this result can then be applied to the averaged splitting as a function of temperature also. The final expression obtained is

$$J(T) = \frac{-3\hbar a}{8\pi m \delta(T)^3} \sqrt{\frac{3}{\pi}} \exp\left[-\frac{3}{4} \frac{a^2 + \lambda^2}{\delta(T)^2}\right] \quad (9a)$$

where

$$\delta(T)^2 = \frac{3h}{4\pi m \nu} \coth\left(\frac{h\nu}{2kT}\right) \quad (9b)$$

Here a is the inter-hydride equilibrium distance, λ is a hard sphere radius (usually taken as 10 nm), ν is the bending frequency of the M–H bonds, and m is the proton mass. When deuterium or tritium is involved, the mass and bending frequency are adjusted accordingly.

Equation (9a) can be used to fit J versus T data, and both a and ν determined. The values found in a large number of fits are quite close to the distances a found by single crystal neutron diffraction and the few ν bending frequencies that have been measured.² For systems with very large ^1H – ^1H exchange interactions, this equation has correctly predicted the size of the ^2D – ^2D exchange couplings when they can be measured. This equation also explains why exchange couplings are not observed in organic molecules. The exchange coupling decreases about two orders of magnitude for every 100 cm^{-1}

increase in ν . Since C–H bends are of the order of 600 cm^{-1} higher than M–H bends, the exchange couplings in organic systems are about 10^{12} smaller and thus unobservable.

Jones and Weitekamp have developed a similar model using numerical diagonalization of model double well potentials.¹² The behavior of J versus T is calculated by a sum over the thermally populated states. One difficulty with this approach is making a connection between the model reaction coordinate and the molecular structure. Harris and co-workers¹³ have studied exchange using muffin-tin-type potentials. They are also able to account for the observed data, and have offered some insight into the types of reaction coordinates that may play an important role.

Limbach¹⁰ has proposed an alternative model to these that is most different in the assumed exchange coordinate. This is a rotational model that produces an exchange splitting from a periodic exchange potential. In the rotational tunneling problem, the tunnel splittings alternate in sign with increasing rotational quantum number. One might then expect that the exchange coupling would have to decrease with temperature in this model instead of increasing as is observed. To circumvent this problem, Limbach proposes that in the ground state the hydrides have no appreciable rotational tunnel splitting. Thermal excitations then allow the system to access a state that is a nascent H_2 complex. The H_2 ligand in this state has a substantial tunnel splitting, which produces the appearance of the exchange coupling. The temperature dependence arises from the thermal population of essentially just the lowest rotational state of the H_2 complex. Such a model can also be used to fit all of the experimental data collected on perprotio systems to date. The main difficulty with this model is rationalizing the existence of an H_2 complex that must lie only 4 – 8 kJ mol^{-1} above the ground state trihydride structure. In addition, the barrier to rotation of the H_2 ligand in the thermally excited state must be well over 40 kJ mol^{-1} to properly account for the apparent tunnel splitting in the lowest rotational state of this nascent H_2 complex.

Differentiation of how well these and other models describe these systems is being tested by several computational groups at present.^{14,15} Potential energy surfaces are calculated for a model system, and the Hamiltonian is then numerically diagonalized. A Boltzmann population-weighted average over the calculated exchange splittings is computed for comparison to the experimentally observed variation of J with temperature. Such calculations can be made to reproduce the trends observed experimentally. However, it remains to be seen how high a level of calculation will be needed to do a better job than the approximate analytical theories.

4 EXAMPLES

A large number of transition metal hydride systems that display exchange couplings have been discovered or rediscovered. One of the most striking is the $\text{Cp}^*(\text{CO})\text{IrH}_3^+$ cation. At 500 MHz, spectra similar to the simulations shown in Figure 3 are observed.¹⁶ This is a deceptively simple AB_2 spectrum, which at first glance is a single line. On closer inspection, one sees that the central line is flanked by two broader lines with integrated intensities of approx. one-tenth of the central peak. This is an example of a dynamically broadened spectrum with a very large $J(^1\text{H}, ^1\text{H})$. The apparent

Figure 3 Simulated AB_2 dynamic 1H NMR spectra similar to what are observed at 500 MHz and about 140 K for the $Cp^*(CO)IrH_3^+$ cation.¹⁶ $J = -2J$ in these simulations is (a) 50 kHz, (b) 25 kHz, and (c) 18 kHz. The central line appears at the weighted average of the A and B chemical shifts. One of the dynamically broadened wings appears at the A-site chemical shift. In comparison with the experimental spectra, only simulations with $J = -2J > 50$ kHz produce a narrow enough central peak. In such cases where $|\nu_A - \nu_B| \ll J$, the central line does not broaden as the decoalescence temperature is reached—rather, only the outer wings narrow. This can lead to the impression that such a molecule is fluxional when in fact it is not

$J = -2J$ must be over 50 kHz as judged from comparison of these simulations with the experimental spectra. This large J lead us to predict that the exchange interaction in the perdeutero system would be of the order of 30–60 Hz and thus observable. Figure 4 shows an example of 2D – 2D exchange coupling observed in this molecule. Simulation of this spectrum requires an exchange coupling. This is because, for spin $I = 1$, the Hamiltonian no longer has the same symmetry as a scalar coupling; therefore, these data cannot be simulated using a scalar coupling network. From the dependence of J on T , one can extract the parameters a and ν , which predict that $J(^1H, ^1H)$ should be approx. 75 kHz, in accordance with the observed 1H spectra. In future, it will be important to find systems in which both the 1H and 2D exchange interactions can be accurately measured as a test of exchange coupling theories.

As a final example, Figure 5 displays some calculated 2D exchange-coupled spectra for AB_2 spin systems with various ratios of exchange coupling to the chemical shift difference. A D_B – D_B scalar coupling has also been included. Note that the scalar coupling between two magnetically equivalent nuclei is now seen to have an effect upon the spectrum! This result is expected, since the D_A – D_B exchange interactions do not commute with the D_B – D_B scalar coupling Hamiltonian, making it possible now to observe it in the spectra.

Figure 4 (a) Experimental 2D NMR spectrum of a mixture of deuterated isotopomers of the $Cp^*(CO)IrH_3^+$ cation (approx. 60% D) at about 145 K. (b) Simulated spectrum giving a D–D exchange coupling between the A and B sites of approx. 40 Hz. Such spectra cannot be fitted using a scalar coupling network

5 SUMMARY

Exchange couplings in solution NMR spectra are manifestations of a purely quantum mechanical effect on the energy levels of sets of identical nuclei in molecules. These effects are related to rotational tunnel splittings in systems such as H_2 or methyl groups, and have the same origins as quantum exchange in solid 3He . The unique feature of exchange coupling in transition metal polyhydride systems is that it persists to relatively high temperatures in the solution phase, making it possible to observe very small exchange splittings by

Figure 5 Calculated ^2D NMR spectra for an AB_2 spin system with scalar and exchange couplings (the chemical shift difference has been set at 400 Hz): (a) no couplings; (b) scalar couplings $J(\text{A}, \text{B}) = 30$ Hz, $J(\text{B}, \text{B}) = 0$; (c) scalar couplings $J(\text{A}, \text{B}) = 30$ Hz, $J(\text{B}, \text{B}) = 100$ Hz; (d) AB exchange coupling $|-2J| = 30$ Hz, scalar $J(\text{B}, \text{B}) = 0$; (e) AB exchange coupling $|-2J| = 30$ Hz, scalar $J(\text{B}, \text{B}) = 100$ Hz. Note that in (c) the inclusion of $J(\text{B}, \text{B}) = 100$ Hz has no visible effect, while the spectrum in (e) is dramatically different from that in (d) when $J(\text{B}, \text{B})$ is introduced

high-resolution NMR. While these splittings are related to tunnel splittings, they do not imply that coherent tunneling motions occur. Rather, they are a consequence of shifts in the orbital energies of the nuclei that are correlated with their spin states. This correlation of spatial and spin variables results in the exchange energy appearing in the transition frequencies observed in NMR spectra.

Acknowledgments

My work in this area has benefited from many interactions with NMR spectroscopists, inorganic chemists, and theoreticians interested in transition metal hydride chemistry. Especially important to me has been my close and very enjoyable collaboration with Professor D. Michael Heinekey and his group. Without his careful attention to experimental detail, the phenomenon of exchange coupling in solution NMR spectra would probably still remain undiscovered.

1 INTRODUCTION

Low-temperature molecular tunneling spectroscopy is of interest for four reasons: it continues into the quantum domain the study of molecular motion, it provides an outstanding example of a classical to quantum transition, it extends NMR and spin thermodynamics into the adjacent domain of coherent molecular dynamics, and finally it clarifies historical conceptual problems concerning particle indistinguishability and the topology of rotation space. The main results have recently been surveyed.¹

The rotations of hindered symmetrical groups like CH₃ and NH₄ in solids persist to helium temperatures where the motion of hindered triangular rotors like CH₃ is characterized by a discrete frequency, the tunnel frequency ω_t , derived from the overlap of ground state librational oscillator wavefunctions localized in adjacent wells of a three-well potential. A typical low-temperature CH₃ spectrum consists of three frequencies: $\pm\omega_t$ and 0. The quantum motion of tetrahedral rotors like NH₄ and ND₄ is more complicated,² with several tunnel frequencies associated with rotation about the different symmetry axes. The structured spectrum changes with increasing temperature towards a Lorentzian peak with a halfwidth $1/\tau_c$, where τ_c is an orientational correlation time. This spectrum is explained by a quasi-classical hopping model. The transition, which has been studied by both magnetic resonance and neutron scattering,³ is illustrated in Figure 1.

2 THE ROTATIONAL SPECTRUM OF A TRIANGULAR ROTOR

2.1 Stationary States

Low-temperature states have well-defined wavenumbers k . The change from well-defined orientation at high temperatures is similar to the change from hopping conduction to band conduction of polarons and excitons. Like these phenomena, molecular rotation is modeled by a particle in a periodic potential with an orientation coordinate ϕ and a hindering potential $V \cos 3\phi$. Special features are due to the finite extent,

Figure 1 The rotational spectrum of a hindered CH₃ group changes from three frequencies $\pm\omega_t$ and 0 at low temperature to a Lorentzian spectrum of rotational hopping motion at high temperature. The figure is a model with a single temperature-dependent parameter that gives a good representation of observations in many materials. The temperature and frequency scales depend on the height of the hindering barrier

2π , of the rotational coordinate space. For stationary states, we assume a cyclic boundary condition $\psi(\phi + 2\pi) = \psi(\phi)$ and the Hamiltonian

$$\hat{\mathcal{H}} = -\frac{\hbar^2}{2I} \frac{\partial^2}{\partial \phi^2} - V \cos 3\phi \quad (1)$$

whose eigenvalues for the lowest band are

$$\hbar\omega(k) = -\frac{2}{3}\hbar\omega_t \cos \frac{2}{3}\pi k \quad (2)$$

The eigenfunctions are Bloch waves with k lying between $\frac{3}{2}$ and $-\frac{3}{2}$. The boundary condition selects $k = \pm 1$ or 0. The energies are thus $-\frac{2}{3}\hbar\omega_t$ and $\frac{1}{3}\hbar\omega_t$, the latter being doubly degenerate. The three frequencies derived from the energy differences are $\pm\omega_t$ and 0, the low-temperature spectrum.

2.2 Excitations and Dynamics

When dynamical interaction with the environment is included, the space ϕ is open and may be envisaged as a helix upon which wavepackets rotate.⁴ A wavepacket confined to one turn of the helix is single-valued within a range 2π and is formed by superposing two of the eigenfunctions of equation (1). Two nodes separated by 2π form the leading and trailing edges of the wavepacket. Three elemental wavepackets rotate with the angular velocities $\pm\omega_t$ and 0. Generation of wavepackets from the stationary states and their subsequent evolution in time can be compared with a 90° pulse and subsequent free induction decay in NMR. The rotation is observable, because it modulates spin-dependent interactions so that molecular rotation and NMR are intimately linked. Thermal excitation results in a transfer of angular momentum, which changes the average wavenumber, $k_a = \pm\frac{1}{2}$ or 0 to

$k_a + \sigma$, $\hbar d\sigma/dt$ being the torque. The general rotation frequency derived from equation (2) is

$$\omega_{k_a, \sigma} = (\frac{3}{4})^{-1/2} \omega_t \sin[\frac{2}{3}\pi(\sigma + k_a)] \quad (3)$$

A distribution of σ explains the broad rotational spectra of Figure 1. Relaxation to stationary states with integer k causes σ to approach zero as the temperature falls.

A wavepacket only has large amplitudes in the potential wells, and can be represented by three complex amplitudes. The three elementary wavepackets can be superposed by adding their amplitudes to form a more general wavepacket whose evolution involves all three frequencies $\omega_{k_a, \sigma}$. This complex wavepacket rotates and oscillates in shape. At low temperature, the frequency 0 is the rotation frequency and the frequencies $\pm\omega_t$ are shape oscillations. Thus the rotor comes to orientational rest, but continues its internal oscillations. This character changes smoothly into one of rotation as σ grows in absolute value. When $\sigma = \frac{3}{4}$, the complex wavepacket rotates clockwise, moving smoothly through each of the three wells in turn. To accomplish the passage between wells, the shape of the wavepacket oscillates in sympathy with the rotation. The coherent evolution of wavepackets for $\sigma = 0$ and $\sigma = \frac{3}{4}$ is compared in Figure 2.

2.3 Combined Spin and Rotational Dynamics

As an alternative to a reference frame in which the lattice is stationary, it is useful to use a frame in which the wavepacket

Figure 2 A methyl group wavepacket is described by three intensities in three potential wells on a circle. At low temperature (a), the wavepacket oscillates in shape without rotating. A rotational impulse changes the motion to one of coherent rotation (b), the correlated shape oscillations now assisting the passage from well to well

is stationary. In this frame, σ appears as a vector potential in the angular momentum operator and the wavenumbers remain integers. Observables are the same whichever frame is used. The vector potential can be incorporated into a spin Hamiltonian to combine quantum rotation and spin dynamics. In the case of a methyl group,

$$\hat{\mathcal{H}} = \hat{\mathcal{H}}_Z + \hat{\mathcal{H}}_{DD} + \hat{\mathcal{H}}_R \quad (4)$$

$$\hat{\mathcal{H}}_R = -\frac{1}{3}\hbar\omega_t(\hat{R}e^{i2\pi\sigma/3} + \hat{R}^{-1}e^{-i2\pi\sigma/3}) \quad (5)$$

where $\hat{\mathcal{H}}_Z$, $\hat{\mathcal{H}}_{DD}$, and $\hat{\mathcal{H}}_R$ are the Zeeman, dipole–dipole, and rotation Hamiltonians. The basis functions are the eight product spin states of three protons at the three lattice sites. These states can be regarded as shorthand for Slater determinants. The operator $\hat{R}$ cyclically permutes the three spin states round the lattice sites. Rotation clockwise through $\frac{2}{3}\pi$ introduces the phase change $\frac{2}{3}\pi\sigma$ and rotation anticlockwise the reverse phase change. Changes in σ arise owing to collisions between one of the methyl protons and a neighboring atom. This formalism can be extended to tetrahedral molecules.

A spin state is propagated by equation (4). The new feature compared with ordinary spin dynamics is inertia. Whereas the precession frequency of a spin depends only on the instantaneous magnetic field, the rotation frequency of a methyl group depends on the previous dynamical history. The evolution involves two coupled equations: the time-dependent Schrödinger equation and the differential equation for σ . For thermal excitations, some stochastic assumption concerning $d\sigma/dt$ must be made. Another torque is due to the angular dependence of the dipole–dipole energy. This can be obtained by rotating the state slightly using $\lambda\hat{R}$, where λ is small, and finding the rate of change of dipolar energy. The change in the dipole–dipole energy due to rotation, familiar at high temperatures, has a low-temperature counterpart in which molecular rotation changes owing to the angular dependence of the dipole–dipole energy.

2.4 The Quantum-to-Classical Transition

The temperature dependence of the rotational spectrum is remarkably similar for all materials except for the scaling of temperature with barrier height. The host lattice serves as a heat bath, destroying coherence and exerting a fluctuating torque. The notable feature is that the outer (shape oscillation) peaks of the low-temperature rotational spectrum move inward with increasing temperature. There have been many theories of this,³ which can be divided (see Section 3) into those that attribute the reduction to properties of the host lattice and those that regard it as an essential feature of the quantum-to-classical transition. The latter view is that the wavepacket shape oscillations slow down to meet the rising rotation rate in order to play their new role of assisting rotation, while fluctuations in the rotation rate broaden the spectrum. The simplest idea⁴ is that the slowing can be described as a spectral averaging process. Orientational hopping is assumed to be accompanied by hopping in k -space. In this way, increasing localization in space is compensated by delocalization in k -space. The frequencies of the low-temperature spectrum are assumed to hop between $\pm\omega_t$ and 0 owing to k modulation,

while each is also subject to random phase modulation due to the changes in orientation. The spectrum is obtained by summing the elements of a matrix $\mathbf{M}^{-1}$, where

$$\mathbf{M} = \begin{bmatrix} i(\omega_l - \omega) - 2\rho - \delta & \rho & \rho \\ \rho & i(-\omega_l - \omega) - 2\rho - \delta & \rho \\ \rho & \rho & -i\omega - 2\rho - \delta \end{bmatrix} \quad (6)$$

Here ρ represents the rate of k hopping and δ the rate of orientational hopping. Both are identified with $1/\tau_c$. At low temperatures, $1/\tau_c \ll \omega_l$, and the frequencies and halfwidths $3/\tau_c$ of the three peaks are obtained from the diagonal elements of equation (6). At high temperatures, ω_l may be neglected. The spectrum is centered at $\omega = 0$, and the halfwidth is $1/\tau_c$. The classical hopping model is thus extended to the quantum regime. Figure 1 is calculated in this way. The parameter $1/\tau_c$ typically obeys an Arrhenius law, and can be roughly equated with a thermal average of the bandwidths of occupied excited librational states. The temperature dependence of the rotational spectrum is thus obtainable from the tunneling frequency without adjustable parameters.

3 FUNDAMENTAL CONSIDERATIONS

3.1 Indistinguishability

Particle indistinguishability has a crucial role in the theory. According to an argument from early quantum theory,⁵ the hindering potential for symmetric molecules must be invariant to the interchange of the space and spin coordinates of the protons. For a methyl group, this means a threefold symmetry,⁶ which prevents excitation of wavepackets and is inconsistent with the high-temperature hopping model. Though the symmetry constraint correctly identifies the stationary states of a hindered methyl group by excluding nonintegral k , it is incompatible with wavepacket dynamics. The reason is that wavepackets and stationary states have different topologies. Consider the evolution from one to the other. A superposition of two similar wavepackets $\psi(\omega t)$ and $\psi(\omega t - \gamma) \exp(\frac{1}{2}i\gamma)$ is a stationary state if $\gamma = (2n + 1)\pi$. As a stationary state is approached, the helical space-time path of the wavepacket broadens, and turns of the helix overlap. The number n of rotations in a time $2\pi/\omega$ becomes ambiguous. Destructive interference between paths of different n restricts k to integral values. When the coordinate ωt disappears, the labels that in wavepacket states refer to nonidentical proton trajectories refer to identical indistinguishable particles. The symmetry constraints with antisymmetrization ensure that the phase is continuous and the Pauli principle is satisfied. Excitations restore the helical space-time topology and the proton trajectories. The constraints no longer strictly apply, but quantum behavior results while wavepackets imperfectly reflect the topology of neighboring stationary states.

3.2 The Topology of Rotation Space

The identification of labels with particles also leads to the identification of molecular rotation with the symmetry operation of permutation. This is only possible if the rotation

space ϕ is closed. Symmetry-constrained theories consequently allow only integral wavenumbers and limit dynamics to transitions that conserve the wavenumber. This makes them completely different from other transport theories, and gives rise to the view that rotation is fundamentally different from translation. The unconstrained theory of Section 2 has affinities with superconductivity, SQUIDs and quantum transport phenomena in general, besides linking with the hopping model of transport.

4 EXPERIMENTS AND TECHNIQUES

The first effect of tunneling rotation to be observed was that motionally narrowed NMR lines of methyl-containing compounds often fail to broaden when the temperature is reduced to 4 K. With falling temperature, the frequency of components of the dipole-dipole interaction converge on $\pm\omega_l$, as in Figure 1, giving rise to discrete sidebands of the NMR spectrum. The total second moment of the NMR spectrum is conserved, so the sidebands are very weak if the tunnel frequency is large. The failure to broaden demonstrates that $\omega_l/2\pi$ exceeds a few tens of kilohertz. ESR studies of free radicals containing rotating methyl groups in the fragment C-CH₃ display more detail. At high temperature, the hyperfine spectrum is a 1 : 3 : 3 : 1 quartet, indicating equal interaction of the electron spin with the three protons. When the temperature is reduced, the spectrum changes to a seven-line pattern 1 : 1 : 1 : 2 : 1 : 1 : 1 with half the spacing of the quartet, the two inner peaks of the quartet having split into 1 : 1 : 1 triplets.⁶ The splitting is due to two of the three methyl states with magnetic quantum number $\frac{1}{2}$ forming stationary wavepackets—one in the orientation that minimizes the hyperfine energy and one in the orientation that maximizes it. The energy difference is the separation of the outer members of the triplet. The central member of the triplet has $k = 0$. The collapse of the outer members of each triplet on to the central member is due to the two wavepackets hopping between the two orientations and averaging the orientationally dependent energy. As the rate of rotation increases, the tunnel frequency falls to join it, as in Figure 1. The effect is that all three members of the triplet are involved in the motional averaging process. This is observed through the fact that the central member of the triplet does not remain narrow, while the outer pair merges with it.

The main ESR transitions correspond to flips of the electron spin, while the nuclear quantum number m remains unchanged. Transitions in which m also changes give rise to weak sideband transitions, which enable the tunnel frequency to be measured with precision. The detection of such transitions, their approximate location having been previously deduced by ENDOR, marked the true beginning of tunneling spectroscopy, the motional spectrum being clearly separate from the pure magnetic transitions. Similar tunneling sidebands of NMR spectra open a frequency window in the region of 200 kHz, rather than the 100 MHz range of ESR. Level crossing or tunnel resonance techniques⁷ greatly aid the detection of weak sideband transitions and extend the range of accessible tunnel frequencies. A magnetic field is chosen such that the molecular tunnel frequency is equal to a Larmor frequency—either the electron Larmor frequency for free radicals or the nuclear Larmor frequency in ordinary materials. At these internal resonances, transfer of energy between magnetic and rotational

energy occurs through a resonant relaxation process. Energy is exchanged between a Zeeman reservoir and a tunneling reservoir, each of which relaxes to the lattice by its own relaxation process. The ideas of spin thermodynamics are extended, and the process provides an extremely sensitive way of detecting tunnel frequencies. It requires the ability to vary the magnetic field. This is done either by changing the NMR measurement frequency or by using field cycling. There are two versions of the technique. In one, the sample is doped with paramagnetic impurities, often by γ irradiation, and the tunnel frequency is tuned to the electron Larmor frequency. In the other, the tunnel frequency is tuned to the nuclear Larmor frequency. Together, these cover the range from a few megahertz to 50 GHz. With paramagnetic impurities, what is observed is a dynamic polarization effect at the magnetic field of the internal resonance. Energy is transferred between the electron Zeeman and tunneling reservoirs when there is a small mismatch in their frequencies, the energy balance being made up by the nuclear Zeeman system, which is heated or cooled according to the sign of the mismatch.

The direct observation of tunneling sideband transitions is generally difficult, because they must be driven with a field that is nonuniform across the molecule. It is the dipole–dipole interaction, mixed into the magnetic states, that drives the transitions. This effect is naturally stronger at low fields. Low-field dipole–dipole driven NMR has consequently proved to be a powerful way of studying tunneling. Either a true low field⁸ using field cycling or a low effective field in the rotating frame⁹ may be employed, and both have given good results. They cover the frequency range from 60 kHz to 1 MHz, and thus link with tunnel resonance methods to provide a spectroscopy covering six decades of frequency. An example of a low-field spectrum is shown in Figure 3. Double resonance techniques can be employed to increase population differences and enhance transitions. The next frontier to still lower frequencies has recently been breached by the use of the Lee–Golburg method of line narrowing. Low-field Fourier transform tunnel spectroscopy is conducted slightly off-resonance in the rotating frame.¹⁰ Another recent development in low-field spectroscopy is the use of SQUID detection.¹¹ It seems likely that developments in the future will come from the increasing exploitation of NMR time domain

Figure 3 The low-field dipole–dipole driven NMR spectrum of dimethylmalonic acid obtained at 4.2 K. The proton Larmor frequency is 210 kHz and the tunnel frequency that splits $m = \frac{1}{2}$ and $-\frac{1}{2}$ levels is 330 kHz

techniques to interchange magnetic and rotational order, using the spins to monitor the coherent tunneling motion.

There are many other phenomena associated with tunneling rotation that a brief review cannot cover, but two observations connected with nearly free rotors should be mentioned. The Haupt effect¹² is a spectacular nuclear dynamic polarization effect that occurs when the temperature of 4-methylpyridine is changed at fairly low temperatures as the slow evolution in the rotational states of the nearly free methyl group drives a large change in the dipole–dipole temperature. The second effect¹³ is the optical observation of fractional quantization of the rotation of nonequilateral triangles of nitrogen atoms in molecular beams. Molecular quantum rotation covers a very wide range of phenomena. Because of its dynamical simplicity, it very clearly exhibits features that are common to all quantum systems.

1 INTRODUCTION

The discovery of the high-temperature superconductors (HTS) in 1986 by Bednorz and Müller¹ unleashed a flurry of scientific activity aimed at understanding and exploiting the novel properties of these materials. Nuclear magnetic resonance has emerged as one of the most important probes of these compounds. NMR studies of the HTS were first motivated by the successful application of NMR to the study of conventional superconductors such as aluminum. In fact, NMR played a central role in the experimental confirmation of the Bardeen–Cooper–Schrieffer (BCS) theory of conventional superconductivity (see the Nobel Prize Lectures by Bardeen, Cooper, and Schrieffer²).

The nature of the HTS heightened the importance of NMR studies. These novel compounds possess extremely complicated unit cells and are very anisotropic. This complicates the analysis of results obtained with nonlocal probes of materials such as specific heat and transport measurements. On the other hand, NMR could be used as a local probe of the electronic properties, since almost every atomic species in the HTS has an isotope with a nuclear magnetic moment. The HTS are also notoriously difficult to grow as a single crystalline phase, and their surfaces are easily modified when exposed to moderate humidity or a vacuum. As a result, surface-sensitive experiments such as tunneling or light scattering frequently gave contradictory results on nominally identical samples in the early years. In contrast, NMR experiments performed around the world yielded results that were in remarkable agreement with one another. The information content and the apparent

reliability of the NMR data led many theorists to concentrate on understanding the implications of the NMR results.

In order to understand the origin of the term ‘HTS’, we list the defining characteristics of conventional superconductors (see, e.g. Tinkham³).

1. T_c : Above this critical transition temperature, a metal (e.g., aluminum) is in the normal state and has all of the properties associated with a normal conductor. When $T < T_c$, the metal is in the superconducting state. The HTS have critical temperatures ranging up to about 125 K—much higher than the conventional superconductor record of $T_c \approx 20$ K.
2. *Perfect conductivity*: below T_c , in the absence of a magnetic field, the resistivity of a superconductor drops to zero, for currents less than a critical current I_c . The HTS also exhibit this effect.
3. *Perfect diamagnetism*: as the temperature is lowered below T_c , weak magnetic fields are expelled from the interior of a superconductor (the Meissner effect). In Type I superconductors, this effect continues until the applied magnetic field exceeds a critical field ($B > B_c$), at which point the sample reverts to the normal state. Type II superconductors exhibit the Meissner effect for $B < B_{c1}$. In the mixed state ($B_{c1} < B < B_{c2}$), the applied field penetrates the sample through a lattice of fluxoids (also known as vortices). When $B > B_{c2}$, the sample is in the normal state. The HTS are extreme Type II superconductors (the coherence length is of order 1 nm and the penetration depth of order 100 nm).
4. *Pairing*: the BCS theory explains conventional superconductivity as a macroscopic quantum state of the electrons in a metal that is brought about by an attractive electron pairing interaction mediated by phonons. Pairing is also found in the superconducting state of the HTS, although the microscopic mechanism for the pairing is not known.

The space limitations and format of this Encyclopedia preclude a comprehensive review of the many NMR studies that have been carried out on the HTS. Instead, this article will describe several representative experiments, which will illustrate the broad range of information that NMR measurements have revealed about the HTS. Several excellent review articles on NMR studies of the HTS may be consulted if the reader wishes to pursue this subject in more detail.^{4–7}

2 PHYSICAL PROPERTIES OF THE HIGH-TEMPERATURE SUPERCONDUCTORS

For a comprehensive review of the physical properties of the HTS, see the three volumes edited by Ginsberg.⁸

2.1 Crystal Structure

The crystal structures of $\text{YBa}_2\text{Cu}_3\text{O}_{7-y}$ (1–2–3) and $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ (2–1–4) are shown in Figure 1. $\text{YBa}_2\text{Cu}_3\text{O}_7$ has $T_c \approx 93$ K, the highest of the 1–2–3 family. Two-dimensional copper oxide planes containing the Cu(2), O(2), and O(3) sites appear in all of the HTS, and it is generally agreed that they are the source of the superconductivity. $\text{YBa}_2\text{Cu}_3\text{O}_7$ has two of these CuO_2 planes separated by the

Figure 1 Crystal structures of (a) $\text{YBa}_2\text{Cu}_3\text{O}_{7-y}$,⁹ (b) $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ ¹⁰

yttrium atom. Below the CuO_2 plane is a layer containing the Ba and O(4) sites, and below that is a layer of one-dimensional CuO chains, which lie along the $\hat{B}$ axis. The Cu(1) and O(1) sites make up these CuO chains. The assignment of the single crystal NMR lines with their respective crystallographic sites was accomplished using this crystal structure. For example, the local environment of the Cu(2) (Cu(1)) site is fourfold symmetric about the $\hat{c}$ axis ($\hat{a}$ axis), which is reflected in the magnetic shift tensor of the site.

$\text{La}_{1.85}\text{Sr}_{0.15}\text{CuO}_4$ has the highest T_c of the 2-1-4 family, $T_c \approx 38$ K. This material is considered by many to be the simplest HTS, since there is only one CuO_2 plane and no CuO chains per unit cell. Unfortunately, it is not easy to perform clean NMR experiments on this compound, since the disorder introduced by the strontium substitution greatly increases the inhomogeneous broadening of the NMR lines.

2.2 Parent Compounds and Doping

All of the HTS are closely related to antiferromagnetic insulators, known as *parent compounds*. For example, $\text{YBa}_2\text{Cu}_3\text{O}_6$, which is obtained by removing all of the oxygen from the O(1) sites in $\text{YBa}_2\text{Cu}_3\text{O}_7$, has a Néel temperature of 400 K. La_2CuO_4 , the parent compound of the 2-1-4 family, has a Néel temperature of 300 K. In these parent compounds, the planar Cu(2) atoms are believed to be Cu^{2+} , with a hole in the $3d_{x^2-y^2}$ state (where $x, y, z = a, b, c$). Each Cu(2) site has a spin- $\frac{1}{2}$, which experiences a strong intraplane antiferromagnetic coupling, along with a much weaker interplane coupling. The parent compounds appear to be two-dimensional Heisenberg antiferromagnets.

As the stoichiometry of these materials is altered, their properties change dramatically. For $\text{YBa}_2\text{Cu}_3\text{O}_6$, this change is effected by adding oxygen in the O(1) site, while for La_2CuO_4 , this change may be accomplished either by adding oxygen ($\text{La}_2\text{CuO}_{4+\delta}$) or by substituting Sr for La ($\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$). These chemical substitutions are thought to add holes to the oxygen 2p orbitals of the CuO_2 planes, which destroy the long-range order and cause the materials to become superconductors. One simple picture of the doped compounds is that the oxygen holes form a conduction band in which

Figure 2 Phase diagrams of (a) $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$,¹¹ (b) $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ (adopted from Figure 2 of Iye¹²)

the Cu(2) moments are imbedded. Alternatively, strong hybridization of the Cu(2) and O(2,3) orbitals might create a single electronic system, with no memory of the magnetic state of the Cu(2) sites in the parent compounds. The NMR data support a picture that is a compromise between these two extremes.

The phase diagrams for 1-2-3 and 2-1-4 are shown in Figure 2. The unusual proximity of the antiferromagnetic phase to the superconducting phase is not yet understood.

2.3 HTS in the Normal and Superconducting States

It is now well established that the HTS are not simple metals. All of the HTS have a strong anisotropy of the normal state conductivity ($\rho_c/\rho_{ab} \approx 10^2-10^5$), so that currents prefer to flow along the CuO_2 planes rather than perpendicular to them. Although angle-resolved photoemission spectroscopy (ARPES) data indicate that a Fermi surface is present, the quasiparticle lifetime does not have the energy dependence expected for a Fermi liquid. The isotropic resistivity of copper metal at room temperature is $\rho_{\text{copper}} = 1.8 \mu\Omega \text{ cm}$, while the

smallest component of the anisotropic resistivity tensor of the ceramic $\text{YBa}_2\text{Cu}_3\text{O}_7$ is $\rho_b = 70 \mu\Omega \text{ cm}$. $\text{YBa}_2\text{Cu}_3\text{O}_7$ also has unusual temperature dependences of both the resistivity ($\rho_{ab} \propto T$, $\rho_c \propto 1/T$) and the Hall effect constant ($R_H \propto 1/T$).

A generalized BCS theory, which allows for a novel pairing mechanism and an unconventional pairing state, describes the superconducting state of the HTS. Measurements of the flux quantum and of Andreev reflection have indicated that the superconductivity involves hole (or electron) pairing. All of the HTS are extreme Type II superconductors, with large anisotropies in the coherence length and the penetration depth.

3 SOLID STATE NMR INVESTIGATION OF METALS AND SUPERCONDUCTORS

3.1 Electric Field Gradient, Magnetic Shift, and Spin–Lattice and Spin–Spin Relaxation Times

Three basic NMR measurements have been used to characterize the HTS. They are measurements of the absorption spectrum, the spin–lattice relaxation time T_1 , and the spin–spin relaxation time T_2 .

The absorption spectrum is a fingerprint of the chemical environment of a nucleus. More explicitly, the energy levels of the nuclei are determined by the following general nuclear spin Hamiltonian,¹³ ignoring nuclear spin–spin couplings:

$$\begin{aligned} \hat{\mathcal{H}} = & -\gamma_n \hbar \sum_{\alpha=x,y,z} \hat{I}_\alpha (1 + K_{\alpha\alpha}) B_{0\alpha} \\ & + \frac{\hbar}{2I(I-1)} [v_{zz}(3\hat{I}_z^2 - \hat{I}^2) \\ & + (v_{xx} - v_{yy})(\hat{I}_x^2 - \hat{I}_y^2)] \end{aligned} \quad (1)$$

The first term is the Zeeman energy of the nuclear magnetic moment ($\hat{I}$ is a dimensionless operator), in the presence of the applied field $\mathbf{B}_0 \parallel \alpha$, where α is one of the unit vectors along the x , y , or z axes. $K_{\alpha\alpha}$ is the magnetic shift tensor, and represents the extra fields produced at the nucleus by the electrons. $|K_{\alpha\alpha}|$ is usually small (typically $< 2\%$). The magnetic shift tensor contains several parts:

$$K_{\alpha\alpha} = K_{\alpha\alpha}^S + K_{\alpha\alpha}^L + \sigma_{\alpha\alpha} \quad (2)$$

The tensor $\sigma_{\alpha\alpha}$ is the shift due to all the closed shell electrons of an atom. Since one usually measures $K_{\alpha\alpha}$ relative to a closed shell reference, we can take $\sigma_{\alpha\alpha}$ to be zero. The tensor $K_{\alpha\alpha}^L$ is called the *chemical shift*, and is due to the extra field at the nucleus contributed by the electronic orbital susceptibility of both the valence electrons of an atom and the closed shell electrons of its neighbors. Thus, the chemical shift is directly proportional to the Van Vleck susceptibility χ^L . The tensor $K_{\alpha\alpha}^S$ is the *Knight shift*, and represents the extra field at the nucleus due to the electronic spin susceptibility χ^S (the Pauli susceptibility in metals). Thus, if one knows or can calculate the constants of proportionality (hyperfine coupling constants), a measurement of $K_{\alpha\alpha}$ yields the values of χ^L and χ^S .¹⁴

The second term in the above static spin Hamiltonian is the quadrupolar interaction. The electric quadrupole moment

of the nucleus couples to the electric field gradient present at the nucleus. Only nuclei with spins $I > \frac{1}{2}$ (e.g. ^{63}Cu , ^{65}Cu , and ^{17}O) can have this term. The tensor $v_{\alpha\alpha}$ gives the $\alpha\alpha$ component of the electric field gradient (in megahertz) at the nucleus due to the electrons in the same atom and the surrounding ions.

We have ignored the nuclear dipole–dipole coupling in this Hamiltonian, because this term is mainly a source of linebreadth for the fields and nuclei in question, and is relatively unimportant for determining the line position or the magnitude of the spin–lattice relaxation.

The above spin Hamiltonian completely determines the NMR absorption spectrum. Once the resonance frequencies are measured, knowledge of the applied field $\mathbf{B}$ and the nuclear spin eigenstates allows one to determine the tensors $K_{\alpha\alpha}$ and $v_{\alpha\alpha}$. For nuclei that have a large quadrupolar term in their Hamiltonian (e.g. copper nuclei in the HTS), a zero field absorption spectrum may be measured using nuclear quadrupole resonance (NQR).

Another informative NMR experiment is a spin–lattice relaxation time T_1 measurement. In the HTS, the nuclear spin–lattice relaxation process is magnetic, so T_1 is determined by the fluctuating magnetic fields at the nucleus, which are perpendicular to the applied field. In these materials, the fluctuating fields are produced by electronic spins that have the periodicity of a Bravais lattice. Thus, following Moriya,¹⁵ the relaxation rate of nucleus i measured with the applied field $\mathbf{B}_0 \parallel \alpha$ is

$$^i \left(\frac{1}{T_1} \right)_\alpha = \frac{^i \gamma_n^2 k_B T}{2\mu_\beta^2} \lim_{\omega \rightarrow 0} \sum_{\mathbf{q}, \alpha' \neq \alpha} |^i A_{\alpha'\alpha'}(\mathbf{q})|^2 \frac{\chi''_{\alpha'\alpha'}(\mathbf{q}, \omega)}{\omega} \quad (3)$$

$\chi''_{\alpha\alpha}(\mathbf{q}, \omega)$ is the imaginary part of the $\mathbf{q}$ - and ω -dependent electronic spin susceptibility tensor (taken to be isotropic in our case), and α are the principal crystalline axes (a, b, c). The limit as $\omega \rightarrow 0$ is taken, because this expression is evaluated at the Larmor frequency of the nucleus, typically around 10 mK, a very small energy on the scale of the electronic spin fluctuations. Note that $(1/T_1)_\alpha$ may be anisotropic if the hyperfine form factors $^i A_{\alpha\alpha}(\mathbf{q})$ are anisotropic. These form factors are completely determined by the real space hyperfine coupling Hamiltonian, which we shall discuss in Section 4.4. The Knight shift is proportional to the real part of the static electronic spin susceptibility, $\chi'_{\alpha\alpha}(\mathbf{q}, \omega = 0)$:

$$^i K_{\alpha\alpha}^S = \lim_{\mathbf{q} \rightarrow 0} [^i A_{\alpha\alpha}(\mathbf{q}) \chi'_{\alpha\alpha}(\mathbf{q}, \omega = 0)] \quad (4)$$

Since the copper nuclei are spin- $\frac{3}{2}$, the recovery of the longitudinal magnetization of a particular resonance line is not, in general, exponential. Nevertheless, the recovery yields a fundamental relaxation rate $W_{1\alpha} \equiv \frac{2}{3}(1/T_1)_\alpha$.

Finally, measurement of the spin–spin relaxation time T_2 may also provide information about the electronic system. Pennington et al.¹⁶ discovered that the decay of the transverse magnetization of the planar copper sites in $\text{YBa}_2\text{Cu}_3\text{O}_7$ is the product of an exponential (arising from T_1) and a Gaussian. The Gaussian component (T_{2G}) is an order of magnitude faster than expected for direct nuclear spin–spin coupling. Pennington et al. postulated that T_{2G} is instead due to an

indirect coupling mediated by the electronic background. Pennington and Slichter¹⁷ showed that T_{2G} may be expressed as a function of $\chi'_{\alpha\alpha}(\mathbf{q}, \omega = 0)$.

3.2 NMR Studies of Metals

In a metal, the nuclear spin–lattice relaxation rate is due to the scattering of conduction electrons by the nuclear spins. The rate is then

$$\frac{1}{T_1} \propto \int_0^\infty |V_{en}|^2 \rho^2(E) f(E) [1 - f(E)] dE \propto T \rho^2(E_F) \quad (5)$$

$\langle V_{en} \rangle$ is the matrix element for the electron–nuclear interaction, $\rho(E)$ is the one-electron density of states, and $f(E)$ is the Fermi function. In this notation, the Knight shift can be written as

$$K^S \propto \int_0^\infty \rho(E) \frac{df(E)}{dE} dE \propto \rho(E_F) \quad (6)$$

Thus, the Knight shift and spin–lattice relaxation time in a normal metal are related:

$$\frac{1}{T_1 T} = \text{const} \times (K^S)^2 \quad (7)$$

This is the *Korringa law*, which has been verified experimentally from 1 K to 930 K in aluminum. The constant is determined by the relevant electron–nuclear couplings, with a small correction of order unity when electron–electron interactions are included.

3.3 NMR Studies of Conventional Superconductors

For a review of this topic, see MacLaughlin.¹⁸

In the BCS theory, for a spin-singlet, orbital s-wave pairing state, the density of excited quasiparticle states is given by

$$\rho_{\text{BCS}}(E - E_F) = \rho(E_F) \frac{|E - E_F|}{\sqrt{(E - E_F)^2 - \Delta^2}} \quad (8)$$

where Δ is an isotropic energy gap which opens up at T_c and is essentially temperature independent for $T/T_c \leq 0.2$. The opening of the gap freezes out thermal excitations, causing $K^S \propto \chi^S \rightarrow 0$ as $T \rightarrow 0$. The temperature dependence of the Knight shift for this pairing state, namely

$$\begin{aligned} \frac{K^S(T < T_c)}{K^S(T = T_c)} &= \int_{-\infty}^\infty \frac{|E - E_F|}{\sqrt{(E - E_F)^2 - \Delta^2}} \left[-\frac{df(E)}{dE} \right] dE \\ &= Y_0(T/T_c) \end{aligned} \quad (9)$$

is conventionally referred to as the *Yosida function*, $Y_0(T/T_c)$.

The T_1 data also show a dramatic deviation from the Korringa law for $T < T_c$. The BCS theory of superconductivity explains that the observed increase in $1/T_1$ just below T_c (the so-called *Hebel–Slichter coherence peak*) is due to both the logarithmic singularity in $\rho_{\text{BCS}}(E - E_F)$ at the edge of the gap and to the BCS coherence factor, which modifies

$|\langle V_{en} \rangle|^2$. The coherence factor reflects the correlated nature of the superconducting ground state, and its experimental confirmation established the validity of the BCS theory.

At low temperatures, when the gap is large and almost independent of temperature, the unpaired electrons that relax the nuclei need to be excited across the energy gap, so

$$1/T_1 \propto \exp(-\Delta/k_B T) \quad (10)$$

Conventional superconductors exhibit a spin-singlet, orbital s-wave pairing state. More generally, the BCS theory could also accommodate a spin-triplet pairing state, which would imply a nonzero trace of the spin susceptibility tensor at $T = 0$. It is also possible to have higher orbital angular momentum pairing states (d-wave, p-wave, etc.), which implies a superconducting energy gap with a lower symmetry than the crystal. Both of these possibilities would be reflected in the temperature dependence of the Knight shift and T_1 below T_c .¹⁹

NMR studies of the mixed state ($T < T_c$, $B_{c1} < B_0 < B_{c2}$) have been carried out in Type II superconductors. The applied field penetrates the interior of the sample through a lattice of fluxoids, which can affect both lineshapes and relaxation rates.

4 NMR STUDIES OF THE HTS IN THE NORMAL STATE

4.1 Sample Characterization Using the Absorption Spectra

Much of the earliest NMR and NQR work focused on determining $K_{\alpha\alpha}$ and $\nu_{\alpha\alpha}$ for the various sites. Pennington et al.²⁰ measured $K_{\alpha\alpha}$ and $\nu_{\alpha\alpha}$ for the Cu(2) and Cu(1) sites in $\text{YBa}_2\text{Cu}_3\text{O}_7$, using a 1 mg single crystal. Their results, shown in Table 1, permitted an unambiguous assignment of the NQR lines. Spin echo pulse sequences with phase cycling were used to acquire spectra and measure relaxation times. The importance of phase cycling is shown in Figure 3.

The electric field gradient at the Cu(2) site is axially symmetric about the $\hat{c}$ axis. Therefore, the nuclear spin eigenstates in an NQR experiment are identical to those in an NMR experiment with $\mathbf{B}_0 \parallel \hat{c}$. The Cu(2) relaxation rate $^{63}\text{W}_{1c}$ may be measured with either experiment.

To explain their shift data, Pennington et al.²⁰ proposed a model that is essentially the permanent moment limit. The copper atom is $\text{Cu}^{2+}(3d^9)$, and the spin- $\frac{1}{2}$ associated with the atom is due to a hole in the $x^2 - y^2$ ($y^2 - z^2$) state for

Table 1 Magnetic Shift and Electric Field Gradient Tensors for the $^{63}\text{Cu}(1)$ and $^{63}\text{Cu}(2)$ sites in $\text{YBa}_2\text{Cu}_3\text{O}_7$ at $T = 100\text{ K}$ ²⁰

	$^{63}\text{Cu}(1)$	$^{63}\text{Cu}(2)$
100 K_{aa}	1.323	0.580
100 K_{bb}	0.561	0.580
100 K_{cc}	0.588	1.267

ν_{bb} (MHz)	+19.18	+15.54
ν_{cc} (MHz)	−0.17	−31.49

Figure 3 The average of 500 000 $^{63}\text{Cu}(2)$ spin echoes from a $\text{YBa}_2\text{Cu}_3\text{O}_7$ sample, showing the importance of phase cycling. The sequences are (a) a single phase Hahn echo, (b) a Hahn echo with add-subtract phase cycling, and (c) a four-phase Hahn echo cycle²¹

the plane (chain) site. The orbital susceptibility of that hole determines the chemical shift K^L , and the Knight shift arises from the hyperfine coupling of the nuclear spin to the Cu^{2+} spin- $\frac{1}{2}$.

A small single crystal sample is difficult to study at high temperatures or in the superconducting state. In these conditions, copper NQR measurements using large (approx. 5 g) powder samples are preferable. The NQR frequency is sensitive to the local environment of the copper sites.

Farrell et al.,²² taking advantage of the anisotropy of the HTS, were the first to make a $\hat{c}$ -axis aligned powder sample. The $\mathbf{B}_0 \parallel \hat{c}$ and $\mathbf{B}_0 \parallel \hat{a}/\hat{b}$ resonances are distinguishable in both aligned powder and single crystal samples, but the large mass of the former results in a superior signal-to-noise ratio. Aligned powder samples have been an absolute necessity in many experiments, such as the measurement of $K_{\alpha\alpha}$ and $\nu_{\alpha\alpha}$ for the $^{17}\text{O}(1)$, $^{17}\text{O}(2,3)$, and $^{17}\text{O}(4)$ sites in $\text{YBa}_2\text{Cu}_3\text{O}_7$ by Takigawa et al.²³

Recently, ^{139}La NMR reported by Hammel et al.²⁴ revealed an interesting phase separation that occurs in $\text{La}_2\text{CuO}_{4+\delta}$. As the single crystal is cooled below $T = 265$ K, the sample develops an antiferromagnetic (oxygen-poor) phase and a metallic (oxygen-rich) phase.

4.2 Magnetic Shift

The magnetic shifts of the Cu, O, and Y nuclei in $\text{YBa}_2\text{Cu}_3\text{O}_7$ are essentially temperature independent in the

Figure 4 The shift ΔK of the ^{89}Y line of $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$, referenced to YCl_3 ($\nu_0 = 15.64$ MHz), plotted versus T , from 77 K to 300 K. The lines through the data for each value of x are guides for the eye²⁵

normal state, as one expects for metals. In general, however, the magnetic shifts of the HTS vary with doping and temperature. Yttrium measurements by Alloul et al.²⁵ in a series of $\text{YBa}_2\text{Cu}_3\text{O}_{6+x}$ samples showed that the magnetic shift is strongly temperature dependent in the normal state for $x \approx 0.4$ – 0.9 , as is shown in Figure 4. In fact, the ^{89}Y magnetic shift is a linear function of the bulk magnetic susceptibility. Alloul et al. inferred that the yttrium nuclei were coupled to the spins associated with the $\text{Cu}(2)$ atoms.

Since the energy scale relevant for the orbital susceptibility is several electron volts, it is thought that the temperature dependence of the bulk susceptibility arises from the electron spin susceptibility. This temperature dependence is referred to as the ‘spin gap’ phenomenon. The name is derived from its two principal manifestations. First, while the spin susceptibility drops dramatically below room temperature, there is no corresponding decrease in the number of charge carriers observed in optical conductivity [$\sigma(\omega)$] measurements. Second, the decrease in the static susceptibility may be parameterized using a simple model with low-lying magnetically inert states separated from excited magnetically active states by a spin gap Δ_{SG} . The magnitude of this gap is $\Delta_{\text{SG}} \approx 200$ K, a very small energy scale compared with the intraplanar exchange coupling $J \approx 1500$ K. The origin of this spin gap behavior is not yet understood theoretically.

Takigawa et al.²⁶ measured the ^{63}Cu and ^{17}O magnetic shifts in a sample of $\text{YBa}_2\text{Cu}_3\text{O}_{6.63}$ with a $T_c = 62$ K. The isotropic magnetic shifts for the $\text{Cu}(2)$ and the $\text{O}(2,3)$ are directly proportional to one another, tracking the temperature-dependent bulk susceptibility, as is shown in Figure 5. This is strong evidence that the $\text{O}(2,3)$ nuclei couple to the same spin susceptibility as the $\text{Cu}(2)$ nuclei. All three planar nuclei apparently couple to a single spin degree of freedom per CuO_2 unit cell, which is associated with the Cu^{2+} hole spin. This is a single component model of the CuO_2 planes.

The lack of evidence for two distinct contributions to the electron spin susceptibility of the CuO_2 planes, one associated with Cu^{2+} spins and one arising from holes doped into the oxygen 2p orbitals, is a puzzle. There are, however, theoretical arguments that the oxygen and copper holes are so strongly

Figure 5 Various components of the $^{63}\text{Cu}(2)$ and $^{17}\text{O}(2,3)$ Knight shifts in $\text{YBa}_2\text{Cu}_3\text{O}_{7-y}$ versus temperature with different vertical scales and origins. The curve is the bulk spin susceptibility for the $y = 0.37$ sample²⁶

coupled that they behave as a single spin degree of freedom at low energies.²⁷

4.3 Spin-Lattice Relaxation Time T_1

Many groups have studied the spin-lattice relaxation times of the Cu(1) and Cu(2) sites in $\text{YBa}_2\text{Cu}_3\text{O}_7$. Comparison of the ^{63}Cu and ^{65}Cu relaxation rates confirms the magnetic origin of the relaxation. The measured rates are surprisingly fast, not only surpassing the expected magnitude of an orbital relaxation rate, but also exceeding the room temperature relaxation rate of copper metal by an order of magnitude.²⁸ The anisotropy of the Cu(2) relaxation rate tensor was measured using single crystal and aligned powder samples. $^{63}W_{1a}$, the relaxation rate measured with the magnetic field applied along the CuO_2 planes, is about four times $^{63}W_{1c}$, the relaxation rate measured with the field along the c axis.

The planar nuclei in $\text{YBa}_2\text{Cu}_3\text{O}_7$ do not share a common temperature dependence. The ^{89}Y and $^{17}\text{O}(2,3)$ relaxation rates are directly proportional to the temperature, as one expects for a simple metal, but the $^{63}\text{Cu}(2)$ rate is not. Figure 6 shows Pennington's NQR measurement of the $^{63}\text{Cu}(2)$ relaxation rate, plotted as T/W_{1c} versus T .²⁹ The straight line fit of the data shows that the $1/T_1T$ obeys a Curie-Weiss law rather than the Korringa law. At $T = 100\text{ K}$, $(^{63}W_{1c}) \approx 10^2 \times (^{17}W_{1c}) \approx 10^4 \times (^{89}W_{1c})$. Imai et al.³⁰ proposed that the anomalously fast Cu(2) relaxation rate reflects the build-up of antiferromagnetic correlations of the Cu(2) spins as the temperature is lowered. In summary, for the planar nuclei in $\text{YBa}_2\text{Cu}_3\text{O}_7$,

$$^{89}W_{1c}/T = A \quad (11)$$

$$^{17}W_{1c}/T = B \quad (12)$$

$$^{63}W_{1c}/T = C/(T + T_\theta) \quad (13)$$

where A, B, C , and T_θ are constants.

The doping dependence is quite complicated at first glance, since the above equations fail to describe the data for any

Figure 6 Temperature divided by the relaxation rate $^{63}W_{1c}$ measured in $\text{YBa}_2\text{Cu}_3\text{O}_7$, plotted versus temperature. The dotted line is a linear fit to the data, confirming equation (13)²⁹

material other than $\text{YBa}_2\text{Cu}_3\text{O}_7$. This is another manifestation of the spin gap phenomenon. Modified versions of equations (11)–(13) can describe the generic behavior of the HTS.⁷ The new expressions for the relaxation rates of the planar nuclei are

$$^{89}W_{1c}/T = A'\chi_0^S(T) \quad (14)$$

$$^{17}W_{1c}/T = B'\chi_0^S(T) \quad (15)$$

$$^{63}W_{1c}/T = C'\chi_0^S(T)/(T + T_\theta) \quad (16)$$

where A', B', C' , and T_θ are constants, and $\chi_0^S(T) = \chi^S(\mathbf{q} = 0, \omega = 0, T)$. For $\text{YBa}_2\text{Cu}_3\text{O}_7$, χ_0^S is independent of temperature, so we recover equations (11)–(13). For $\text{YBa}_2\text{Cu}_3\text{O}_{6.63}$, equations (14)–(16) are appropriate, as we see in Figure 7.³¹

Figure 7 Temperature dependence of $^{63}W_{1c}/T$ (●) and $^{17}W_{1c}/T$ (○) in $\text{YBa}_2\text{Cu}_3\text{O}_{6.63}$ (taken from Figure 4 of Takigawa³¹). The solid line shows the temperature dependence of the spin susceptibility for this material, confirming (15) and (16)

4.4 Single Component Model for the CuO₂ Planes

Consideration of the shift and relaxation rate data presented in Sections 4.1–4.3 led to the creation of a single component model for the CuO₂ planes. In YBa₂Cu₃O₇, the hyperfine coupling Hamiltonian for the ⁶³Cu(2), ¹⁷O(2,3), and ⁸⁹Y is

$$\hat{\mathcal{H}} = \sum_{\alpha=a,b,c} \left(A_{\alpha\alpha} {}^{63}\hat{I}_{\alpha}^i \hat{S}_{\alpha}^i + \sum_j B {}^{63}\hat{I}_{\alpha}^i \hat{S}_{\alpha}^i + \sum_l C {}^{17}\hat{I}_{\alpha}^k \hat{S}_{\alpha}^l + \sum_n D {}^{89}\hat{I}_{\alpha}^m \hat{S}_{\alpha}^n \right) \quad (17)$$

The first term is the anisotropic on-site coupling of the i th ⁶³Cu(2) nucleus to the Cu²⁺ hole spin in the 3d_{x²-y²} orbital, proposed by Pennington et al.²⁰ to explain the anisotropic tensors ⁶³W_{1a} and ⁶³K_{αα}. The hyperfine tensor $A_{\alpha\alpha}$ includes both the magnetic dipolar and core polarization coupling. Takigawa et al.³² showed that an additional term is required for the ⁶³Cu(2), because the isotropic Knight shift is positive. To explain this observation, Mila and Rice³³ proposed that the i th ⁶³Cu(2) nucleus experiences a large, isotropic transferred hyperfine coupling B to the four nearest neighbor Cu²⁺ spins in the same plane (the j sites). B arises from the overlap of the nearest neighbor copper spin ($x^2 - y^2$) orbital with the unfilled 4s orbital of the on-site Cu(2) atom, mediated by the intervening O(2,3) 2pσ orbitals. When $\mathbf{B}_0 \parallel \hat{\mathbf{c}}$ the ⁶³Cu(2) magnetic shift in the HTS is temperature independent, even when the spin susceptibility is temperature dependent, implying that $A_{cc} + 4B \approx 0$.

The third term in the Hamiltonian, equation (17) is the transferred hyperfine coupling C of the k th ¹⁷O(2,3) nucleus to the two nearest neighbor Cu spins (the l sites). The fourth term is the hyperfine coupling of the m th ⁸⁹Y nucleus to its eight nearest neighbor Cu²⁺ spins (the n sites): four in the plane above and four in the plane below. In this *single* component model, there is no coupling to an electronic spin associated with holes doped into the planar oxygen orbitals.

The spin–lattice relaxation of the planar nuclei is due to fluctuations of the Cu²⁺ spins. Shastry³⁴ and Hammel et al.³⁵ pointed out that the symmetry of the hyperfine Hamiltonian in equation (17) can explain the different temperature dependences of the Cu(2), O(2,3), and Y relaxation rates. For example, antiferromagnetic alignment of the Cu²⁺ spins results in a nonzero hyperfine field at the ⁶³Cu(2) site, while the field at the ¹⁷O(2,3) or ⁸⁹Y sites vanishes. Thus, antiferromagnetic spin fluctuations may contribute quite strongly to the relaxation rate of the Cu(2), but not to the relaxation rate of the O(2,3) or Y. In this model, the relaxation rate for each site is¹⁵

$$\left(\frac{1}{T_1} \right)_{\alpha} = \frac{i\gamma_n^2 k_B T}{2\mu_{\beta}^2} \lim_{\omega \rightarrow 0} \sum_{q, \alpha'=\alpha} |^i A_{\alpha\alpha'}(q)|^2 \frac{\chi''_{\alpha'\alpha'}(q, \omega)}{\omega} \quad (18)$$

This expression is valid for $i = 63, 17$, and 89 [Cu(2), O(2,3), and Y], the only difference being the quantity $|^i A_{\alpha\alpha'}(q)|$, which is the q -space Fourier transform of the real space hyperfine coupling constants. This form factor $|^i A_{\alpha\alpha'}(q)|$ acts as a filter, determining which spin fluctuation wavelengths contribute to the relaxation rate.

Figure 8 Each hyperfine form factor (left side) multiplied by $\chi''(q, \omega)$ (top) yields a uniquely q -dependent product (right side). These products, plotted here along the Brillouin zone diagonal [$q (= q_x = q_y)$], enter into the expression for the relaxation rate, equation (18)³⁶

The differences between the various $|^i A_{\alpha\alpha'}(q)|^2$ are shown in Figure 8. For our purposes, the most important regions of the two-dimensional Brillouin zone are large q [$q \approx Q = (\pi/a, \pi/a)$, corresponding to antiferromagnetic fluctuations], and small q ($q \approx 0$, corresponding to long-wavelength fluctuations). The relaxation rates, in order of decreasing sensitivity to the $q \approx Q$ region of $\chi''(q, \omega)$, are ⁶³W_{1a}, ⁶³W_{1c}, ¹⁷W_{1c}, and ⁸⁹W_{1c}. To illustrate this, we show the products $|^i A_{\alpha\alpha'}(q)|^2 \chi''_{\alpha'\alpha'}(q, \omega)$ in Figure 8 for q along the zone diagonal, using a generic form for $\chi''(q, \omega)$, which has a big peak at $q = Q$ [due to antiferromagnetic correlations of the Cu(2) electronic spins]. If this big peak had a different temperature dependence from the $q = 0$ region, the Cu(2) relaxation rates would have a different temperature dependence from the O(2,3) and Y relaxation rates, as is experimentally observed.

The hyperfine couplings we have discussed so far and their implications within a one-component model are widely accepted concepts. However, the actual form chosen for $\chi''(q, \omega)$ and the microscopic justification for that form is a much more controversial issue. One particular model, proposed by Millis, Monien, and Pines (MMP),³⁷ achieved great success in quantitatively fitting the normal state data (K^S and T_1). An acknowledged problem with this successful model is the reconciliation of the MMP $\chi(q, \omega)$ with inelastic neutron scattering measurements. It is important to note

that the neutron scattering measurements probe $\chi''(\mathbf{q}, \omega)$ at finite ω , while the NMR experiments are only sensitive to $\chi''(\mathbf{q}, \omega \approx 0)$.

Although the single component model works very well, two recent experiments have concluded that the model is not complete. Takigawa et al.³⁸ measured the ^{89}Y relaxation rate in $\text{YBa}_2\text{Cu}_3\text{O}_{6.63}$, which deviates slightly from equation (14). Their results are consistent with the build-up of antiferromagnetic correlations between adjacent CuO_2 layers as the temperature is lowered. In another experiment, Walstedt et al.³⁹ have measured the planar copper and oxygen relaxation rates in $\text{La}_{1.86}\text{Sr}_{0.14}\text{CuO}_4$. They compared these data with rates calculated using the single component model and the $\chi''(\mathbf{q}, \omega)$ measured in neutron scattering. While there is rough agreement with the copper data, they are unable to fit the planar oxygen data. They suggest that the assumptions of the single component model need to be reexamined.

4.5 The Gaussian Contribution to T_2

Pennington et al.¹⁶ discovered that the $\text{Cu}(2)$ transverse magnetization decay was the product of an exponential and a Gaussian, for $\mathbf{B}_0 \parallel \hat{c}$. A $^{63}\text{Cu}(2)$ – $^{65}\text{Cu}(2)$ SEDOR experiment was used to isolate the Gaussian contribution cleanly, as is shown in Figure 9. In order to characterize the temperature dependence of $\chi(\mathbf{q}, \omega)$, Imai et al.⁴⁰ measured T_{2G} along with T_1 as a function of temperature in $\text{YBa}_2\text{Cu}_3\text{O}_7$.

Imai et al.⁴¹ also measured T_{2G} and T_1 of the $\text{Cu}(2)$ site in La_2CuO_4 from $T = 450\text{ K}$ to 900 K . These measurements confirm that La_2CuO_4 is a two-dimensional Heisenberg antiferromagnet. When Imai et al.⁴² extended their T_1 measurements of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ to high temperatures, they found that both the superconductor ($x = 0.15$) and the

Figure 9 The $^{63}\text{Cu}(2)$ – $^{65}\text{Cu}(2)$ SEDOR (spin echo double resonance) pulse sequence (inset) and data (main figure). The echo size is plotted versus $2T_{\text{flip}}$. The solid line is a Gaussian with $\tau_{\text{SEDOR}} = 130\text{ }\mu\text{s}$ ¹⁶

Figure 10 Temperature dependence of $1/^{63}\text{T}_1$ for various doping levels of $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ ⁴²

antiferromagnet ($x = 0$) exhibited the same temperature-independent T_1 , as is seen in Figure 10. This surprising result shows that doped holes are clearly not determining the spin dynamics at high temperatures.

5 NMR STUDIES OF THE HTS IN THE SUPERCONDUCTING STATE

5.1 Test of the Pairing State

Given the unusual properties of the HTS in the normal state, it is reasonable to question whether a generalized BCS pairing state provides an appropriate description of the superconducting state. At present, no alternative theory has been developed to the point where its predictions may be compared with the NMR data. Comparisons of superconducting state data with the predictions of a generalized BCS theory have led to the conclusion that the pairing state is a spin singlet, and that the orbital pairing state is not conventional s-wave. Determining the pairing state symmetry is important, because the answer is linked to the microscopic mechanism for the pairing (for example, phonon-mediated pairing is usually associated with an isotropic s-wave state, while pairing mediated by antiferromagnetic spin fluctuations is usually associated with an orbital d-wave state.)

5.1.1 Knight Shift

The temperature dependence of the ^{63}Cu Knight shift $K^S(T)$ in $\text{YBa}_2\text{Cu}_3\text{O}_7$ below T_c is the most direct evidence that the pairing state is a spin singlet.⁴³ The experiment involves a measurement of the temperature-dependent line positions $\nu_{\text{Cu}}(T)$. Recall that the positions of the ^{63}Cu NMR resonance lines are given by

$$\nu_{\text{Cu}}(T) = \text{const} \times [1 - K^L + K^S(T)]B_{\text{int}}(T) + \nu_Q(T) \quad (19)$$

An accurate measurement of $K^S(T)$ therefore requires knowledge of the internal field $B_{\text{int}}(T)$ and the quadrupolar contribution to the resonance frequency, $\nu_Q(T)$. The uncertainty in

$B_{\text{int}}(T)$ has been the traditional weakness of Knight shift measurements. In the mixed state ($B_{c1} < B_0 < B_{c2}$), $B_{\text{int}} \neq B_0$ because of superconducting diamagnetic screening currents. Indeed, there will be a spread in the values of B_{int} , which will cause an inhomogeneous broadening of the NMR line.

Fortunately, $B_{\text{int}}(T)$ may be determined quite accurately in $\text{YBa}_2\text{Cu}_3\text{O}_7$ using the ^{89}Y NMR as an internal field marker. Since ^{89}Y is spin- $\frac{1}{2}$, and its shift is known to be small compared with that of the copper ($K_Y < \frac{1}{10}K_{\text{Cu}}$), the line position of the ^{89}Y is

$$\nu_Y(T) = \frac{\gamma_Y}{2\pi} [1 + K_Y(T)] B_{\text{int}}(T) \approx \frac{\gamma_Y}{2\pi} B_{\text{int}}(T) \quad (20)$$

The problem with this approach is that the yttrium signal in this material is quite weak because the gyromagnetic ratio γ_Y is small and because the low temperature yttrium relaxation time is extremely long (approx. 10 min at 4.2 K). Barrett et al.⁴³ used a Carr–Purcell–Meiboom–Gill pulse sequence to speed up data acquisition by a factor of 6, making the experiment feasible. Their results for the temperature-dependent magnetic shift tensor of the Cu(2) and Cu(1) are shown in Figure 11.

The Knight shift tensor $K_{\alpha\alpha}^S(T)$ is related to the magnetic shift tensor $K_{\alpha\alpha}(T)$ by

$$K_{\alpha\alpha}(T) = K_{\alpha\alpha}^L + K_{\alpha\alpha}^S(T) \quad (21)$$

If the pairing state is a spin singlet then $K_{\alpha\alpha}^S(T=0) = 0$. The low temperature magnetic shift values are then just the chemical shift values $K_{\alpha\alpha}(T=4.2\text{ K}) = K_{\alpha\alpha}^L$. The chemical shift is given by

$$K_{\alpha\alpha}^L = 2\beta^2 \left[\sum_n \frac{\langle 0 | \hat{L}_\alpha | n \rangle \langle n | \hat{L}_\alpha / r^3 | 0 \rangle}{E_n - E_0} + \text{c.c.} \right] \quad (22)$$

Thus, the normal state result that the electronic state of the Cu(2) (Cu(1)) is very close to Cu^{2+} with a single d-shell hole in the $x^2 - y^2$ ($y^2 - z^2$) state predicts that²⁰

$$K_{cc}^L \geq 4K_{aa}^L = 4K_{bb}^L \quad \text{for the Cu(2)} \quad (23)$$

Figure 11 The total ^{63}Cu magnetic shift as a function of temperature for (a) the Cu(2), and (b),(c) the Cu(1) sites in $\text{YBa}_2\text{Cu}_3\text{O}_7$ ⁴³

Table 2 Comparison of the Theoretical Chemical Shift Anisotropy in $\text{YBa}_2\text{Cu}_3\text{O}_7$ with the Experimental Anisotropy Implied by Spin-Singlet Pairing²⁰

		Theory	Experiment
$^{63}\text{Cu}(1)$	K_{aa}^L/K_{bb}^L	≥ 4	4.00
	K_{aa}^L/K_{cc}^L	≥ 4	4.32
$^{63}\text{Cu}(2)$	K_{cc}^L/K_{aa}^L	≥ 4	4.57
	K_{cc}^L/K_{bb}^L	≥ 4	4.57

$$K_{aa}^L \geq 4K_{bb}^L = 4K_{cc}^L \quad \text{for the Cu(1)} \quad (24)$$

From Table 2, we see that the experimental results assuming spin-singlet pairing are in quite good agreement with these predictions.

On the other hand, if the pairing state is a spin triplet then some components of the Knight shift tensor will not vanish when $T = 0$. In particular, if the trace of the spin susceptibility tensor is $3\chi_n^S$ at $T = T_c$ then it is $2\chi_n^S$ at $T = 0$.¹⁹ Therefore, $K_{\alpha\alpha}(T = 4.2\text{ K})$ would have a large contribution from $K_{\alpha\alpha}^S(T = 4.2\text{ K})$, which would imply unphysical values for $K_{\alpha\alpha}^L$. This analysis leads to the conclusion that the pairing state is a spin singlet, and $K_{\alpha\alpha}(T = 4.2\text{ K}) = K_{\alpha\alpha}^L$.

The temperature dependence of the Knight shift is also informative. For the Cu(2) sites, the rapid drop in $K_{bb}^S(T)$ just below T_c together with its weak temperature dependence below $T \approx 30\text{ K}$ imply a strong-coupling energy gap, i.e., the gap opens up faster and goes to a larger value than predicted by the original BCS weak-coupling theory. The Knight shift temperature dependence does not rule out either orbital s-wave or orbital d-wave pairing.⁴³

5.1.2 Spin–Lattice Relaxation Time T_1

For every nucleus investigated in the HTS, there is no coherence peak in the NMR (or NQR) relaxation rate below T_c . In addition, $1/T_1$ does not follow equation (10), as expected for a BCS spin-singlet, orbital s-wave pairing state. Instead, Imai et al.⁴⁴ fit their $(1/T_1)_{\text{NQR}}$ data to a T^3 form over two decades (see Figure 12). Several groups suggested that these results implied either a strong pair breaking mechanism or an unconventional superconducting state.

Another probe of the pairing state is the temperature dependence of the Cu(2) relaxation rate anisotropy ratio, $^{63}W_{1a}/^{63}W_{1c}$. In the normal state, this ratio is about 3.7 in $\text{YBa}_2\text{Cu}_3\text{O}_7$, independent of temperature. This result arises from the different form factors for $^{63}W_{1a}$ and $^{63}W_{1c}$, as described in Section 4.4. Barrett et al.²⁹ showed that $^{63}W_{1a}/^{63}W_{1c}$ dropped suddenly below T_c . Figure 13 compares the low field $^{63}W_{1a}/^{63}W_{1c}$ measurements of Martindale et al.⁴⁵ and Takigawa et al.⁴⁶ with calculations by Bulut and Scalapino.⁴⁷ Bulut and Scalapino conclude that the Cu(2) anisotropy ratio favors an orbital d-wave pairing state over an isotropic s-wave state. The anisotropy ratio is sensitive to the orbital symmetry of the pairing state (i.e., the q dependence of the superconducting energy gap) because of the q -dependent form factors $|^iA_{\alpha\alpha}(q)|$. Similarly, $^{63}W_{1c}$ and $^{17}W_{1c}$ have been measured in weak fields by Martindale et al.⁴⁸ (see Figure 14), and the observed temperature dependence has been explained

Figure 12 ^{63}Cu NQR spin-lattice relaxation rate data plotted versus temperature on a log-log scale.⁴⁴ For a BCS d-wave pairing state, one expects that $1/T_1 \propto T^{-3}$ as $T \rightarrow 0$

Figure 13 Plot of $^{63}W_{1a}/^{63}W_{1c}$ in $\text{YBa}_2\text{Cu}_3\text{O}_7$ versus T/T_c . The open squares are the weak-field data of Martindale et al.,⁴⁵ and the open and filled circles are the data of Takigawa et al.⁴⁶ The solid curve is Bulut and Scalapino's⁴⁷ d-wave calculation with $2\Delta_{\text{max}}(0) = 8k_B T_c$, the dotted curve is their s-wave calculation with $2\Delta(0) = 4k_B T_c$, and the dashed curve is their s-wave calculation with $2\Delta(0) = 8k_B T_c$

by Thelen et al.⁴⁹ using a $d_{x^2-y^2}$ orbital pairing state and a Fermi surface consistent with photoemission data.

5.1.3 The Gaussian Contribution to T_2

Itoh et al.⁵⁰ have measured T_{2G} in the normal and superconducting states of $\text{YBa}_2\text{Cu}_4\text{O}_8$. Their results, shown in Figure 15, compare favorably with the predictions of Bulut and Scalapino⁵¹ for orbital d-wave pairing.

It is important to point out that the T_1 and T_{2G} measurements do not require that the orbital symmetry of the pairing state must be $d_{x^2-y^2}$. For example, an extremely anisotropic

Figure 14 W_{1c} measured in a 0.67 T field versus temperature on a log-log scale.⁴⁸ The $^{63}\text{Cu}(2)$ and $^{17}\text{O}(2,3)$ data in $\text{YBa}_2\text{Cu}_3\text{O}_7$ are shown as circles and squares, respectively. The inset contains the same data plotted in an alternate form

Figure 15 Plot of the Gaussian contribution to the spin-spin relaxation rate $1/T_{2G}$ versus temperature. The open circles are the data for $\text{YBa}_2\text{Cu}_4\text{O}_8$.⁵⁰ The solid curves are the calculations of Bulut and Scalapino,⁵¹ assuming s-wave (S) and d-wave (D) pairing states

s-wave state may also account for the temperature dependence of the NMR data. Rather, the NMR results show that the pairing state is a spin singlet, with a highly anisotropic energy gap.

5.2 Studies of the 'Mixed State'

Mehring et al.⁵² have observed the fluxoid-induced broadening of the ^{205}Tl NMR line in $\text{Tl}_2\text{Ba}_2\text{CuO}_6$ ($T_c = 85$ K), which they use to infer the low-temperature penetration depth. Several groups have used ^{89}Y and ^{205}Tl NMR measurements to study fluxoid dynamics in the HTS.

Martindale et al.^{45,48} discovered that $^{63}W_{1c}$ and $^{17}W_{1c}$ are field dependent at low temperatures in $\text{YBa}_2\text{Cu}_3\text{O}_7$. The field dependence of $^{63}W_{1a}$ is much weaker. Martindale et al. suggested that fluxoids may be responsible for the field

dependence of the relaxation rates. Corey et al. (R. Corey, personal communication) studied the angular dependence of these rates, concluding that fluxoids do contribute to the relaxation at low temperatures.

6 SUMMARY AND FUTURE DIRECTIONS

NMR and NQR studies of the HTS continue to provide important information about the normal and superconducting states. Experimentalists and theorists from around the world have contributed to our current deep understanding of the wide range of behavior exhibited by these compounds. Nevertheless, there are many important open questions.

In the normal state, both the NMR and neutron scattering measurements confirm the presence of short-range antiferromagnetic spin correlations, even in the superconducting compounds. However, the detailed shape of $\chi''(\mathbf{q}, \omega)$ that gives the best fit to the NMR experiments is not consistent with the $\chi''(\mathbf{q}, \omega)$ measured by inelastic neutron scattering.

In the superconducting state, the pairing state seems to be a generalized BCS spin singlet, with a highly anisotropic energy gap. This conclusion, however, is based primarily upon measurements of $\text{YBa}_2\text{Cu}_3\text{O}_7$ and $\text{YBa}_2\text{Cu}_4\text{O}_8$, which are quite similar to one another. Superconducting state NMR measurements should be carried out in additional compounds, to refine our knowledge of the superconducting pairing state.

1 INTRODUCTION

Nuclear magnetic resonance is a useful tool with which to investigate certain important aspects of superconductivity. It has played an historic role in understanding the properties of superconductors. The environment of nuclear spins in a metal is greatly modified when a metal makes the transition into the superconducting state. The nuclear spins are sensitive to this variation, leading NMR to be an important technique as a probe of the superconducting state.

In a metal, the static response to an external magnetic field in the normal state is generally expressed by a bulk diamagnetic susceptibility. The same mechanism also contributes to the Knight shift of the NMR frequency in a metal.

The dynamic coupling between a spin system and its surroundings (the lattice) gives rise to lattice-induced transitions between spin states. The nuclear spin–lattice relaxation time T_1 is a measure of the rate of exchange of energy between a spin system and the rest of the lattice. It is most generally defined as the ratio of the deviation of spin energy from its equilibrium value to the time rate of change of spin energy.

The Knight shift and T_1 are two important quantities which give much information about the properties of conduction electrons. In particular, T_1 provides information on the density of states near the Fermi surface. Accordingly, it is expected that both effects provide a test of any theory of superconductivity.

Hebel and Slichter¹ first measured T_1 in aluminum, which was believed to be a well-behaved superconductor, in parallel with the development of the Bardeen, Cooper, and Schrieffer² (henceforth referred to as BCS) theory in 1957, which gave a microscopic understanding of superconductivity. They calculated the relaxation time predicted by the BCS theory, and found that their experimental T_1 data were consistent with the theory. In fact, T_1 measurements together with measurements of acoustic absorption provide an important confirmation of the choice of spin pairing of the BCS wavefunctions (the so-called ‘coherence effect’). The agreement of the nuclear relaxation time with theory is in contradiction to the behavior of the Knight shift, which remains finite in the superconducting state at absolute zero,^{3,4} a result that was difficult to explain in any simple way.

Independently, Redfield⁵ and later Masuda and Redfield⁶ measured T_1 in superconducting aluminum with greater

accuracy and over a wider temperature range, from which important information on the existence of an energy gap can be obtained. It was obvious that the nuclear T_1 values would be worth knowing, but these measurements were even more interesting than had been anticipated; they were in striking contrast to any two-fluid model of superconductivity, but could be easily explained by the BCS theory, assuming an energy gap at temperature $T = 0$ of $2\epsilon_0(0) = 3.2k_B T_c$ and a constant relative anisotropy of the energy gap, where T_c is the critical temperature. Studies of the superconducting state by NMR are summarized in detail elsewhere.⁷

2 KNIGHT SHIFT IN THE SUPERCONDUCTING STATE

2.1 Experiments on Elemental Superconductors

Soon after the appearance of the BCS theory, experiments on the ¹⁹⁹Hg Knight shift in mercury colloids³ and the ¹¹⁹Sn Knight shift in tin platelets were performed.⁴ The results for both Hg and Sn metals indicated the existence of a residual Knight shift at $T = 0$. These experiments seemed to contradict the BCS hypothesis of singlet spin pairing in the superconducting ground state. A number of explanations appeared to find a way out of this dilemma, involving ideas such as modified pairing criteria and even triplet spin pairing. To explain the experiments, however, a serious modification of the BCS picture was unnecessary.

In nontransition metals the Knight shift is due mainly to the hyperfine contact interaction, and is proportional to the normal state Pauli spin susceptibility χ_n . By making use of the BCS theory, Yosida⁸ calculated the spin susceptibility in the superconducting state and derived an expression for the Knight shift in the superconducting state.

In the superconducting state all ground state pairs are either occupied or unoccupied, and therefore the contribution to the spin susceptibility will only come from excited states, the populations of which are given by a Fermi function $f(E_k)$ of the excited state energy E_k . Accordingly, the spin susceptibility in the superconducting state is given by

$$\chi_s = -2\mu_B^2 \sum_k df/dE_k \quad (1)$$

where μ_B is the Bohr magneton and k the wavevector. By making use of the BCS energy density of excited states $N_{\text{BCS}}(E, T)$, the sums in equation (1) can be converted to integrals as follows,

$$\chi_s = -4\mu_B^2 \int_{\epsilon_0(T)}^{\infty} N_{\text{BCS}}(E, T) (df/dE) dE \quad (2)$$

Here $N_{\text{BCS}}(E, T)$ is given by

$$N_{\text{BCS}}(E, T) = \begin{cases} 0 & \text{for } |E| < \epsilon_0(T) \\ N(0)|E|/[E^2 - \epsilon_0^2(T)]^{1/2} & \text{for } |E| > \epsilon_0(T) \end{cases} \quad (3)$$

where $N(0)$ is the normal state density of states at the Fermi level. The χ_n value is obtained by taking $\epsilon_0(T) = 0$.

Figure 1 Spin susceptibility in pure superconducting aluminum. Filled circles: data of Fine et al.¹⁰ Solid curve: calculated from the theory of Yosida,⁸ l is the electron mean free path, and t is the average thickness of a single substrate

The early experiments of the ^{27}Al Knight shift showed that the Knight shift in the superconducting state at temperature $T = 0$, $K_s(T = 0)$ decreases to about 75% of its values in the normal state, K_n . This result suggested that a residual spin susceptibility, was conceivably due to an inclusion of paramagnetic impurities, since no other mechanism suggested itself. Hammond and Kelly⁹ repeated the measurement of the ^{27}Al Knight shift on stacked Al films, taking care to eliminate paramagnetic oxygen impurities in the film. The experimental result of $K_s(T)/K_n$ extrapolated to zero at $T = 0$, as shown in Figure 1,¹⁰ and the longstanding discrepancy between experiment and the prediction of singlet spin pairing, was thereby finally removed. Further experiments on the residual Knight shift in both tin and lead revealed that the spin-orbit coupling is induced in the conduction-electron gas by the boundary in small particles as well as imperfections, and the generalized pairing condition between time-reversed eigenstates might account for the small change of the Knight shift in the superconducting state.

2.2 Various Contributions to the Knight Shift

The conduction-electron susceptibility in the normal state of a metal consists of three important contributions: the s-band Pauli susceptibility in the case of a simple metal; the Van Vleck orbital susceptibility in transition metals with partly filled non-s bands; and the Pauli susceptibility of the non-s (usually d) bands in the case of transition metals. Each mechanism produces a shift component proportional to the corresponding susceptibility. The orbital shift is independent of the spin state of the conduction electrons, and hence does not change by spin pairing in the superconducting state. The contribution of the exchange interaction between non-s itinerant electrons and local s core electrons to the Knight shift should cancel each other out in the superconducting state if the d-band electrons take part in the formation of Cooper pairs.

The residual ^{51}V Knight shift in superconducting vanadium films is found to be intrinsically 100% of the normal state shift. This result indicates that the Knight shift due to the s-band

Pauli susceptibility and the Pauli susceptibility of the non-s bands must cancel each other, so that even if spin pairing is complete in the superconducting state, the effect on the measured Knight shift is small; the orbital shift is the principal contribution in both normal and superconducting states.

Susceptibility and Knight shift measurements on the inter-metallic compounds V_3Si and V_3Ga show that an increase of the ^{51}V and ^{71}Ga Knight shifts seen in the superconducting state can be attributed to a decrease of the d-band spin susceptibility at $T = 0$ to about 25% of its value at the critical temperature. V_3Si has the A15 crystal structure, in which an extremely narrow d-band exists. This crystal structure enhances the d-band susceptibility, which increases the Knight shift to well above its value in pure vanadium.

3 NUCLEAR SPIN-LATTICE RELAXATION IN BCS SUPERCONDUCTORS

3.1 Spin Relaxation due to the BCS Mechanism

The nuclear spin-lattice relaxation rate $R = 1/T_1$ in a type-I superconductor can be calculated within the framework of the BCS theory. The dominant mechanism for this relaxation process arises from the coupling of the nuclear spins I to the conduction electron spins σ , which are in equilibrium with the lattice, and the hyperfine contact interaction.

The matrix elements between excited states of the system are given by a single particle operator of the form

$$\hat{\mathcal{H}}_1 = \sum_{k\sigma, k'\sigma'} M_{k\sigma, k'\sigma'} \hat{a}_{k'\sigma'}^* \hat{a}_{k\sigma} \quad (4)$$

where $M_{k\sigma, k'\sigma'}$ is the matrix element corresponding to scattering from $k\sigma$ to $k'\sigma'$ and $\hat{a}_{k\sigma}^*$ and $\hat{a}_{k'\sigma'}$ are creation and destruction operators for quasiparticle excitations in the normal state. In the Bloch approximation, individual particle wavefunctions, $\phi_{k\sigma}(x)$, are defined for a self-consistent field. In this situation, therefore,

$$M_{k\sigma, k'\sigma'} = \int \phi_{k'\sigma'}^*(x) \hat{\mathcal{H}}_1(x) \phi_{k\sigma}(x) dx \quad (5)$$

in which x is defined to include the spin variable.

The significant feature of the BCS picture is the condensation of conduction electrons into a single, occupied ground state. In a pure metal this state corresponds to a pair occupation of the Bloch states $k\sigma$, such that if $k\sigma$ is occupied, so is $-k, -\sigma$ in the pair. At $T = 0$ all electrons occupy pair states; at finite temperature some pairs are broken up to form single-particle excitations. Nevertheless the coherent occupation of the condensed state restricts the scattering processes, and in addition alters the number of excited state electrons that can participate in scattering. Both these effects disappear in the normal state.

A remarkable difference between the superconducting and normal states arises from coherent effects associated with the paired wavefunctions. In the normal state scattering from $k\sigma$ to $k'\sigma'$ is completely independent of scattering from $-k', -\sigma'$ to $-k, -\sigma$, as well as of all other transitions. The probability of the former is proportional to $|M_{k\sigma, k'\sigma'}|^2$, and

the latter is $|M_{-k', -\sigma', -k, -\sigma}|^2$. Because of the nature of the paired wavefunction in a superconducting state, these two contributions to the matrix elements for transition probabilities in a superconducting state are coherent and therefore may add destructively or constructively.

The ground-state occupation changes the transition rate for scattering, in such a way that the transition rate in the normal state is modified by the factor

$$C_{\pm}(E_k, E_{k'}, T) = \frac{1}{2}[1 \pm (\epsilon_0^2(T)/E_k E_{k'})] \quad (6)$$

where E_k and $E_{k'}$ are the initial and final excited state energies, respectively. $C_{\pm}(E_k, E_{k'}, T)$ is the coherence factor, as it represents concretely the coherent nature of the population of pair states in the formation of the condensed phase. The sign of the second term in equation (6) depends on the nature of the perturbation which induces the transition. If the interaction is invariant under time reversal applied to the conduction-electron system, the minus sign is appropriate, namely $C_{-}(E_k, E_{k'}, T)$. This is the case for phonons; in the case of ultrasonic attenuation, there is a very rapid drop in attenuation versus temperature at T_c , followed by a more gradual decrease. If the perturbation is not time-reversal invariant, $C_{+}(E_k, E_{k'}, T)$ is appropriate. The nuclear spin relaxation rate exhibits an increase by a factor of 2 just below T_c which gives an indication of coherence effects arising from constructive interference.

Consider, for simplicity, that $I = \frac{1}{2}$, and that an experiment is performed in a magnetic field with nuclear Zeeman energy $\hbar\omega_{\text{nuc}}$. Then the relaxation rate is given by $W_{+} + W_{-}$, where W_{+} is the transition rate from spin-up to spin-down nuclear states induced by the entire conduction-electron system, and W_{-} is the rate for spin-down to spin-up transitions. The relaxation rates are given by

$$W_{\pm} = \frac{\pi}{2\hbar} |M_{k\sigma, k'\sigma'}|^2 \sum_{k, k'} C_{\pm}(E_k, E_{k'}, T) f(E_k, T) \times [1 - f(E_{k'}, T)] \delta(E_{k'} - E_k \mp \hbar\omega_{\text{nuc}}) \quad (7)$$

where the Fermi distribution function $f(E_k, T)$ accounts for the thermal population of excited initial states, and $[1 - f(E_{k'}, T)]$ gives the thermal depopulation of final states required by the Pauli principle. The delta function insures the conservation of total energy in the scattering process.

By making use of the density of states in the superconducting state $N_s(E_k, T)$, the sums in equation (7) can be converted to integrals. The relaxation rate in the superconducting state R_s is given by

$$R_s \propto \int_0^{\infty} N_s(E_k, T) N_s(E_{k'}, T) [1 + \epsilon_0^2(T)/E_k E_{k'}] f(E_k, T) \times [1 - f(E_{k'}, T)] dE_k \quad (8)$$

The BCS theory shows that the superconductor has a temperature-dependent gap of halfwidth $\epsilon_0(T)$ centered about the Fermi energy E_F . If the difference in energy between final and initial electron states is ignored, then the ratio of relaxation rates in superconducting to normal states, R_s/R_n , is given by

$$R_s/R_n = 2 \int [N_s(E, T)]^2 [1 + \epsilon_0^2(T)/E^2] f(E, T) \times [1 - f(E, T)] dE \quad (9)$$

There is actually a logarithmic divergence of the integral in the limit $\hbar\omega_{\text{nuc}} \rightarrow 0$. This divergence comes from the singularity in the BCS density of states at the edge of the energy gap. The values of T_1 in the superconducting state predicted directly by the BCS theory are thus much shorter than those observed, and much shorter than T_1 in the normal state, near T_c . In comparing the theory with experiment it is necessary to take some sort of width for the electronic levels. It is reasonable that in actual metals the singularity will be removed by some mechanisms, and it is possible to see that spin-lattice relaxation measurements can yield information on the nature of such mechanisms.

Hebel and Slichter¹ obtained N_s by weighting the BCS density of states, N_{BCS} , with a function that characterizes the breadth of the energy levels. If an energy level breadth function is assumed to be a rectangle of width 2Δ and height $\frac{1}{2}\Delta$, then

$$N_s(E, T) = (2\Delta)^{-1} \int_{E-\Delta}^{E+\Delta} N_{\text{BCS}}(E', T) dE' \quad (10)$$

Using equation (9), we can calculate the temperature dependence of T_1 for various values of $r = \epsilon_0(0)/\Delta$. Actually, of course, the parameter Δ might be temperature dependent. Now, as T approaches T_c the gap $2\epsilon_0(T)$ decreases, and it would be natural to assume that the anisotropy decreases and is perhaps proportional to the gap, as pointed out by Masuda and Redfield.⁶ In that case we would have $\Delta(T)$ proportional to $\epsilon_0(T)$.

A field cycling method was used to measure T_1 . In this method a large field is applied across the sample to polarize the nuclei (about 0.4 T in this case) for a time long compared with T_1 . The field is then reduced to zero in a time that is short compared with T_1 , and the spins begin to relax at zero field in the superconducting state with a relaxation time characteristic of the superconducting state. After a variable time τ , the field is then turned on again (to about 0.1 T) and immediately swept past the present resonance field of 0.1045 T to observe the spin polarization in the normal state by nuclear resonance. The resonance intensity is proportional to the spin polarization at that time and from its variation of the resonance signal intensity with τ , the relaxation time can be determined.

The nuclear resonance signal obtained in this way is much smaller than that observed above T_c because the nuclei are partially irreversibly demagnetized by the sudden change in magnetic field to which they are subjected when the transition takes place between the normal and superconducting states. For the sample used in most of these measurements, the signal was reduced to less than 5% of the value it would have had in a similar nonsuperconductor after the same sequence of field cycling.

The data for the relaxation time in both normal and superconducting states are shown in Figure 2 as a function of T_c/T .⁶ The fact that T_1 decreases markedly just below T_c , and then increases as $\exp[\epsilon_0(0)/k_B T]$ for $T \ll T_c$ is a rather general consequence of any gap model. As can be seen from Figure 2, superconducting aluminum has an energy gap at $T = 0$ of $2\epsilon_0(0) = 3.2k_B T_c$, assuming that the BCS density of states function is smeared over a range of about $\Delta(T) = \epsilon_0(T)/10$, or $r(T) = 10\epsilon_0(0)/\epsilon_0(T)$. The BCS theory applies to the homogeneous, pure, and isotropic electron gas with a simplified interaction term and pure plane wavefunctions. If,

Figure 2 Measured values of T_1 in a powdered, pure aluminum sample.⁶ T_c was taken to be 1.178 K. The solid line was calculated using the BCS density of states smeared over a range of 1/10 of the energy gap, assuming a smearing proportional to the energy gap

instead of the constant electron–electron interaction, one were to use wavefunctions and an electron–electron interaction that is nonconstant and anisotropic (as might be expected in actual metals), one would expect to find that the energy gap is a function of momentum vector, as well as temperature. Thus, the energy gap of a single particle excitation would depend upon the direction, as well as the magnitude, of its momentum vector. But nuclear spin relaxation has no momentum selection rule for the initial and final states of the transition, so the average density of states determines T_1 , not the density of states in any particular k direction. Thus, as far as spin relaxation is concerned, the effect of anisotropy is to smear the BCS density of states by an amount equal to the anisotropy.

These experimental data are regarded as evidence for the existence of an anisotropy in the energy gap which, at any temperature, is of the order of one-tenth of the gap itself. The quantity $\Delta(T)$ could be interpreted in some other way, such as an inverse lifetime for scattering by imperfections or electrons. However, the temperature dependence of Δ or r is most naturally explained in terms of anisotropy. The anisotropy interpretation is also supported by the results described in the next section.

Measurements of T_1 in superconductors were extended to cadmium,¹¹ for which the behavior is practically identical with that of aluminum.

3.2 Impurity Effects: Anisotropy of the Energy Gap

The T_1 data of both superconducting aluminum and superconducting cadmium were explained very well by assuming a smearing of the anisotropy of the gap as mentioned above. To confirm this assumption experimentally, T_1 in superconducting aluminum alloys was measured.¹²

Figure 3 Measured values of T_1 in Al–Zn alloys.¹² T_c was taken to be 1.178 K. The solid lines are calculated using the BCS density of states smeared over a range of 1/10, 1/40, and 1/60 of the energy gap, assuming a smearing proportional to the energy gap

In a dilute alloy, plane-wave states with fixed spin are no longer good one-electron wavefunctions. Anderson¹³ developed a BCS type of theory for dirty superconductors, in which elastic scattering from physical and chemical impurities is large compared with the energy gap. He argued that a ground-state pair should be formed by pairing a one-electron state with its exact time reversed. This state is a generalization of the k up, $-k$ down pairing of the BCS theory, which is independent of impurity scattering. If the electronic mean free path is large compared with the coherence length, the impurities will mix plane-wave states weakly as the electron moves through a coherence length. However, when the mean free path is small compared with the coherence length, the wavefunction can no longer be approximated by a single plane wave. Thus, the states are taken more or less randomly from all parts of the Fermi surface, thereby removing this source of anisotropy in the energy gap.

The experimental data on Al–Zn alloys are shown in Figure 3. The data on the 0.036 at% Zn alloy agree well with theory, assuming $r(T) = 40\epsilon_0(0)/\epsilon_0(T)$ and using the same energy gap $2\epsilon_0(0) = 3.2k_B T_c$ as that used in pure bulk aluminum (solid line). Data on the 0.055 at% Zn alloy show that a numerical factor in $r(T)$ increases from 40 to 60 but the energy gap remains the same. Roughly speaking, the increase of the numerical factor is proportional to the inverse mean free path $1/l$.

As we add impurities, the individual momentum states are scattered around the Fermi surface. Therefore, the angular dependence of the energy gap is removed from the individual excitation energy gap. If Δ represents an anisotropy of the energy gap present in pure aluminum, Δ decreases (or r increases) as the impurity concentration increases. For sufficiently small concentrations of impurities, the experimental data indicate that r increases linearly with increasing reciprocal mean free path. This apparent linear increase of r with l^{-1}

may be fortuitous, since the accuracy of the present determination of r is poor. Presumably the quantity r^{-1} is a measure of the anisotropy.

Data on a 0.16 at% Ge alloy indicate that the width of the energy gap will be close to the value predicted by BCS theory in the case of constant interaction. Once the mixing is complete, the effect on superconductivity should saturate. If we could measure T_1 in very impure samples without quadrupolar effects, the saturation value of r might be observed. But, as T_1 is proportional to $\log r$ for $T \ll T_c$, it would be hard to determine r correctly.

The theory of energy gap anisotropy in dirty superconductors was given by Clem.¹⁴ The gap parameter in the direction θ can be defined as

$$\epsilon_0(\theta) = \langle \epsilon_0 \rangle [1 + a(\theta)] \quad (11)$$

where $a(\theta)$ is the anisotropy function which describes the variation of the gap over the Fermi surface due to anisotropy in the phonon spectrum or the band structure, and $\langle a(\theta) \rangle = 0$. The density of excited states is calculated as a function of the impurity scattering mean free path, or specifically of the ‘dirtiness’ parameter

$$y_D = [2\epsilon_0(0)\tau]^{-1} = 1.57\xi_0/l \quad (12)$$

where τ^{-1} is the mean frequency of scattering processes and ξ_0 the coherence length. In the dirty limit, $y_D \gg 1$, the density of states approaches the singular BCS form, and by making use of the mean square anisotropy $\langle a^2 \rangle$, becomes a universal function of the parameter $\eta_s = y_D/\langle a^2 \rangle$. The anisotropy-induced structure in the density of states will disappear in the dirty limit.

3.3 Size Effect: Fluctuations in the Order Parameter

Measurements of the Knight shift in superconductors must, of necessity, be made on samples that are small compared with the penetration depth in order that variations in the Knight shift will not be confused with the shift due to the Meissner effect. In contrast to the Knight shift, measurements of T_1 are in good agreement with the BCS theory; these measurements have been made on ‘bulk’ samples, that is, powders with individual particles that are large compared with the coherence length. In view of the disagreement between the Knight shift measurements and the BCS theory, it seemed interesting to see if there is an anomaly in the relaxation time as well, when the particle size becomes small compared with the coherence length or the penetration depth. This was the motivation for performing experiments on the size effect.¹⁵ However, the experimental results obtained surpassed our expectations and suggested an important and interesting fact of superconductivity, which is yet to be theoretically understood.

Particles of aluminum having diameters of less than 2000 Å were prepared by vaporizing aluminum in an atmosphere of argon at a pressure of a few hectopascals. Then the relaxation time T_1 was measured by using the field cycling method in the normal and superconducting states between 0.36 and 1.3 K. In the normal state, and near T_c , the relaxation time was nearly the same as for bulk aluminum, which is evidence that the particles are indeed metallic.

Figure 4 Measured relaxation times T_1 in pure aluminum colloid, the diameter of which ranges from 200 to 700 Å¹⁵

Typical T_1 results for the sample with the most uniform particle size distribution (200–700 Å) are shown in Figure 4.¹⁵ The relatively small change in T_1 in the normal state, compared with the bulk sample, may be the result of an imperfection-induced quadrupole interaction. However, such a change was not observed when small amounts of impurities were added to bulk samples, so the change may be a true size effect.

Kubo¹⁶ discussed the specific heat and spin susceptibility of small particles, but probably his conclusions did not apply to particles as large as those used here. It is interesting to note that the electronic level spacing in the particles is large compared with $\hbar/T_1$, in violation of the condition for the validity of time-dependent perturbation theory. This difficulty can probably be ignored since the electronic levels are broadened by interaction with lattice vibrations, so that the system, electrons plus lattice, has a higher density of states than the electrons alone.

Turning to the superconducting state, the zero field measurements can be fitted to a theoretical curve according to the procedures applied to the bulk metal described before. Well below T_c , the zero field relaxation time is shorter than that of bulk aluminum, being less than one-fifth the bulk value at 0.4 K, and indicates a gap of the order of one-half the BCS value. Thus, an important size-dependence of T_1 was found, but these results could not be explained in a satisfactory way at that time, and were forgotten. About 10 years later, this relaxation behavior was explained by considering the effects of fluctuations of the order parameter in small specimens. The first observation, made in 1967,¹⁷ attributed to fluctuations, was an increase in conductivity just above T_c in thin films. A theoretical explanation of the observation was given in 1968.¹⁸ A reduction in the size of specimens should increase the effect of fluctuations in the order parameter. Therefore, the most suitable specimens for the observation of the size effect are small isolated particles.

Maki et al.¹⁹ first considered the effect of fluctuations on nuclear spin–lattice relaxation in superconductors in the mean field regime. They found an expression for the relaxation rate

Figure 5 Reduced relaxation time $T_1/T_{1n}(T_c)$ as a function of inverse reduced temperature, reduced pair-breaking parameter α/T_c , and particle size parameter $\bar{\delta}$. Light solid curves: unrenormalized theory of Maki et al.¹⁹ Heavy solid curves: renormalized dirty-limit theory of Simánek et al.²¹ Open circles and triangles: experimental results of Masuda and Redfield (annealed and unannealed aluminum colloids, respectively). The diameter ranges from 200 to 700 Å¹⁵

above T_c in the presence of fluctuations given by,

$$R_s/R_n = 1 + [\pi T_c/4N(0)v\alpha(H)(T - T_c)] \quad (13)$$

where v is the particle volume and $\alpha(H)$ a pair-breaking parameter. Pair-breaking may be due to paramagnetic impurities, an applied magnetic field, or, in the absence of external perturbations, the small, spatial variation of the order parameter near the particle surface. According to equation (13), the relaxation rate diverges as $(T - T_c)^{-1}$ at $T = T_c$ as shown in Figure 5. This divergence is removed by allowing the normal electrons to be dressed with fluctuation-induced Cooper pairs. Using this picture, the spin-lattice relaxation rate was calculated.²⁰ The effect of renormalization of the normal electrons by fluctuations extended over a much wider temperature range than interactions between fluctuations themselves. Thus, the divergent behavior was removed.

The temperature dependence of R_s shows a smooth behavior in the region of T_c for all values of v and $\alpha(H)$. The size parameter is defined as $\bar{\delta} = 1/N(0)vT_c$. For small $\bar{\delta}$ a characteristic peak is obtained in the relaxation rate just below T_c . As $\bar{\delta}$ is increased, this peak is smeared out, and the rate decreases monotonically with decreasing temperature for $\bar{\delta} \lesssim 1$. For $\alpha(H) \neq 0$, the position of the peak is depressed to lower temperatures if $\bar{\delta} \ll 1$, and for $\bar{\delta} \lesssim 1$ the effect of additional pair breaking is a small increase in R_s . These results are shown in Figure 5.²¹

This theory is not appropriate for very small particles ($\bar{\delta} \gtrsim 1$), since here the level quantization imposed by the boundary conditions on the electronic wavefunctions at the particle surfaces splits the electronic energy levels by an amount comparable to T_c . This effect is important for Al and Sn particles of less than 50 Å in diameter.^{22,23} The

theory, in which the combined effect of fluctuations and level quantization are taken into account, is quite complicated.²⁴

4 NMR IN TYPE-II SUPERCONDUCTORS

4.1 Magnetic Field Distribution in the Mixed State

A change in NMR properties in the mixed state is caused by the penetration of a magnetic field into a type-II superconductor by means of a periodic lattice of fluxoids, or vortices. Conventional NMR studies of the field distribution are difficult because of the large resonance linewidths, baseline drift, and noise due to vortex motion. To avoid these difficulties the same field cycling method as that used in superconducting aluminum was used. This method has the advantage that the signal can be observed in the normal state with less noise and baseline drift.²⁵ In the case of type-II superconductors the magnetic field was not reduced to zero but switched to a value below H_{c2} during a time τ which was fixed at about 0.1 s. During the time τ a transverse rf field $H_p \cos(2\pi\nu_p t)$, the probe field, was applied perpendicular to H_c . In order to measure the effect of the probe field, the decrease in this subsequent signal reflecting the NMR absorption was measured as a function of the probe frequency ν_p . Typical subsequent signals are shown in Figure 6.

The original calculation on the vortex lattice structure performed by Abrikosov assumed a square lattice. The first direct evidence for the vortex lattice was a neutron diffraction experiment and it was concluded that the lattice must be

Figure 6 Raw lineshape data at various fields and power levels in type-II superconducting vanadium²⁵

Figure 7 Theoretical resonance lineshapes.²⁵ The inset shows a unit cell of the triangular vortex lattice, showing points of maximum field (V), minimum field (C), and the saddle point (S)

triangular. The first calculation of the NMR lineshape was performed for a square fluxoid lattice and appeared to conflict with the NMR data. The theoretical resonance lineshapes for the triangular and square lattice are shown in Figure 7. The calculation was performed on the basis of a solution to the Ginzburg–Landau equation in the Abrikosov limit. The difference between the positions of the singularity for the square and triangular lattice is a general result of geometry plus the assumption that field and current cannot vary in space over a coherence length. The inset shows a unit cell of the triangular vortex lattice, showing points of maximum field (V), minimum field (C) and the saddle point (S). For the square lattice, the saddle point in real space is equidistant from the nearest vortex and the nearest minimum point. For the triangular lattice, in real space, the saddle–vortex distance (S–V) is $\sqrt{3}$ times greater than the saddle–minimum distance (S–M). Thus the saddle point field also tends to be closer to the minimum field, an effect that is much greater than the real space distance ratio suggests, because the field and current must vary smoothly in space.

The theoretical lineshapes in Figure 7 were convoluted with a Gaussian function to smear out the lineshapes by about 10%, in order to agree with the width of the end of the line at high field, and then normalized to obtain good agreement with experiment for the triangular lattice, as shown in Figure 8. The experimental points are proportional to $-\ln \{[S(H_p) - S(\infty)]/[S(0) - S(\infty)]\}$, where $S(H_p)$ is the signal observed when the probe field equals H_p , $S(0)$ is that with no probe field, and $S(\infty)$ is the signal at very high probe power, which is mostly due to repolarization of the spin system during the time the field is turned on, just before observation, at 0.6 T. If one makes a simple spin-temperature assumption about the rate of energy absorption, then one concludes that this transformation of the data should give the absorption lineshape that would be observed in conventional NMR. The excellent agreement between these points and the triangular lineshape should not be taken too seriously, since there were three parameters varied to fit the data (width, height, smearing), but it would not be possible to change these parameters to get nearly as good agreement with the square lattice curve. Closer to H_{c2} it would be harder to make this distinction. For very low magnetic field, however, one has essentially an array

Figure 8 Comparison between theoretical lineshapes obtained by smearing the shapes of Figure 7, with the absorption lineshape deduced from the data of Figure 6²⁵

of nearly isolated vortices, and the peak is expected to move toward the lower end of the line for any arrangement.

Similar work using a standard continuous-absorption technique was performed by Delrieu and Winter.²⁶ They observed the ^{73}Nb resonance in superconducting niobium near H_{c2} , directly, and found a field distribution with the singularity near the minimum field value, as predicted for the triangular lattice, which agrees well with the conclusion by Redfield.

4.2 Nuclear Magnetic Relaxation in Type-II Superconductors

The nuclear spin–lattice relaxation time, T_1 , in a type-I superconductor in zero magnetic field is determined mainly by the high density of states above the energy gap. For a type-II superconductor, the energy dependence of the density of states in the mixed state slightly below the upper critical field H_{c2} differs considerably from that in the BCS state. In the Abrikosov description of type-II superconductors in the mixed state, an external magnetic field penetrates into the specimen as quantized flux, called fluxoids or vortices. In the region of a fluxoid, the order parameter is appreciably reduced from its zero field value, approaching zero at the flux center. This reduction in the order parameter may be reflected in the density of states near the Fermi surface and hence the behavior of the nuclear spin relaxation rate.

Measurements of T_1 in a type-II superconductor were expected to add information to the picture of the mixed state. In earlier studies in the mixed state, most T_1 measurements were made far below H_{c2} and T_c .²⁷ This situation corresponds to the case of well-separated vortices. In the absence of vortex motion and spin diffusion, the nuclear spins located far from vortex lines certainly see quasiparticle excitation in a superconductor, and at low temperatures will show BCS behavior. Spins within the coherence length ξ_0 of a vortex

line relax rapidly with a rate comparable to the normal state value. When both spins contribute significantly to the signal, nonexponential decays will be observed. Experiments on Nb–Zr alloys indicate that the slow decay component of the signal, which is attributed to the spins located far from vortices, shows BCS behavior. In this case, the spatial fluctuations of the energy gap are considered to be localized near the flux center and most of the sample has an energy gap which is essentially equal to that in zero external field. As the temperature decreases T_1 begins to deviate from the BCS value appreciably. The field-dependent deviation from the BCS theory was attributed to a relaxation mechanism involving spin diffusion to the vortex cores. In the subcritical region slightly below H_{c2} , the distance between vortices becomes comparable to the coherence length ξ_0 . In this region, the order parameter $\epsilon_0(r)$ is small and a gapless excitation spectrum is expected to appear. It is therefore likely that the nuclear relaxation in this region will show interesting features.

The T_1 of ^{51}V in an intermetallic compound V_3Sn was measured by pulsed NMR in the temperature range 1.2–77 K.²⁸ The measurements were carried out at the center of the resonance from 0.4470 to 1.3410 T for frequencies of 5, 10, and 15 MHz. The Korringa relationship $T_1 T = 420 \text{ ms} \cdot \text{K}$ was well fitted by the experimental points taken in the normal state over the temperature range 1.8–77 K for a magnetic field of 1.3410 T. At the critical temperature corresponding to this field (1.8 K), T_1 showed no minimum as the temperature decreased but it increased monotonically compared with the Korringa time.

The experimental results in the range 1.2–4.2 K are shown in Figure 9 in the form of the ratio R_s/R_n as a function of $T/T_c(H)$, at a fixed magnetic field. $T_c(H)$ is the critical temperature corresponding to the resonance field H . As can be seen from Figure 9 in the case of $T_c(0) > T_c(H) > 0.6T_c(0)$, a maximum in $R_s(T)/R_n(T)$ appears at $T/T_c(H) = 0.9$ in both cases of 0.4470 and 0.8940 T, but the magnitude of this maximum is dependent on the applied field strength. However, in the case of $T_c(H) < 0.6T_c(0)$, $R_s(T)/R_n(T)$ shows no maximum as the temperature decreases, but it decreases exponentially. This effect of magnetic field on the relaxation behavior suggests that a pair-breaking mechanism due to magnetic field enters into the coherence factor.

Griffin and Ambegaokar²⁹ have extended the calculation of the nuclear spin relaxation rate to a superconductor in the presence of magnetic impurities. The conclusion that the coherence factor is due to the nature of the magnetic hyperfine coupling between the electrons and the nuclear spins is important. The superconductor containing magnetic impurities is a perfect diamagnet in an external magnetic field even in the gapless region. The fundamental property of superconductivity is thus the existence of a pair correlation rather than that of an energy gap. The most important effect of superconductivity appears only through the coherence factors. It is known that paramagnetic impurities and magnetic fields have similar effects on many physical quantities in superconductors. In these two situations the coherence factors are equivalent. This equivalence is established only for the second-order term in $\epsilon_0(r)$ and significant deviations are expected to arise in the fourth order terms. The depairing by the magnetic field or by impurities enters into the coherence factors and these pair-breaking mechanisms are equivalent in both cases. Starting

Figure 9 Reduced ^{51}V relaxation rate in the superconducting mixed state of V_3Sn . The relaxation rate for a magnetic field of 1.3410 T decreases monotonically with temperature²⁸

from this point of view, Maki and Fulde³⁰ obtained the results equivalent to those derived by Griffin and Ambegaokar.²⁹

The ratio of the nuclear spin relaxation rates in a dirty type-II superconductor in the gapless region to those in the normal state were obtained by Cyrot³¹ using a perturbation calculation in powers of $\epsilon_0(r)$. He obtained the following result,

$$\frac{R_s}{R_n} = 1 + \frac{\langle |\epsilon_0(r)|^2 \rangle}{2(2\pi k_B T)^2} [\rho^{-1} \phi^{(1)}(\frac{1}{2} + \rho) + 3\phi^{(2)}(\frac{1}{2} + \rho)] \quad (14)$$

where $\rho = D_e H / (2\pi k_B T)$, D is the diffusion coefficient, and $\phi^n(\rho)$ is the n th derivative of the digamma function. If we substitute the expression for $\langle |\epsilon_0|^2 \rangle$, following Abrikosov, equation (14) in the case of spherical samples can be represented as follows:

$$\frac{R_s}{R_n} = 1 + \frac{ec}{8\pi^2 \sigma k_B T_c(0)} - \frac{H_{c2} - H}{[2\kappa_2^2(t) - 1]\beta_A + \frac{1}{3}} C(t) \quad (15)$$

where σ is the normal state conductivity, c the velocity of light, $\kappa_2(t)$ the temperature-dependent parameter which appears in the expression for the magnetization, $\beta_A = 1.16$, and $C(t)$ is a dimensionless function of reduced temperature $t = T/T_c(0)$ given by

$$C(t) = (\rho t)^{-1} \left[1 + 3\rho \frac{\phi^{(2)}(\frac{1}{2} + \rho)}{\phi^{(1)}(\frac{1}{2} + \rho)} \right] \quad (16)$$

The temperature dependence of $C(t)$ was numerically calculated, and depicted in Figure 10. In the range of $t = 0$ to 0.6, $C(t)$ has a negative value and crosses zero at $t = 0.6$. As the

Figure 10 Dependence of the universal function $C(t)$ on the reduced temperature $t = T/T_c$. The gradient dR_s/dH of the relaxation rate at H_{c2} is proportional to $C(t)$ in the mixed state of dirty type-II superconductors³¹

temperature increases above $t = 0.6$, $C(t)$ becomes positive, and then diverges near $T_c(0)$.

As can be understood from equation (16), in the range of $H_{c2} - H \ll H_{c2}$ and for temperatures close to $T_c(H)$, the relaxation rate in the superconducting state is larger than that in the normal state. For temperatures far below $T_c(H)$, the relaxation rate in the superconducting state becomes smaller than R_n . At $0.6T_c(0)$ both rates have the same value. This behavior agrees with the experimental result that at about $T = 0.6T_c(0)$ the slope of the relaxation rate passes through zero.

The theoretical prediction of the initial slope of the relaxation rate at $T_c(H)$ for the magnetic field, in which the relaxation rate is measured, is given by the following equation:

$$\left. \frac{1}{R_n} \frac{\partial R_s}{\partial T} \right|_{T=T_c(H)} = \frac{ec}{8\pi^2 \sigma k_B T_c(0)} \left. \frac{\partial H_{c2}(T)}{\partial T} \right|_{T=T_c(H)} C(t) \quad (17)$$

The calculated result described above agrees with experiment quite well at low temperatures. However, a deviation appears near $T_c(0)$. One of the reasons for this deviation may be the broadening of the BCS state due to energy gap anisotropy.

4.3 Magnetic Impurity Effects in Type-II Superconductors

Magnetic impurity effects, studied by NMR in metals and alloys, give much information about the electronic states of conduction electrons. In normal metals and alloys, various paramagnetic impurity-induced relaxation mechanisms exist, in addition to the usual Korringa process. They are the relaxation due to the fluctuating local dipole fields associated with the longitudinal and transverse fluctuations of the localized magnetic impurity dipole moment (the LD and TD mechanisms); and the indirect Rudermann–Kittel–Kasuya–Yosida coupling between the localized magnetic impurity moment and nuclear spins via conduction-electron systems. The latter relaxation mechanism is associated with the real or virtual excitation of the localized magnetic impurity moment (the RE and VE mechanisms), respectively.

Superconductivity is strongly affected by the presence of magnetic impurities. The Korringa mechanism in superconductors has been investigated theoretically within the framework of the Abrikosov and Gor'kov (AG's) depairing theory by Griffin and Ambegaokar.²⁹ The LD, TD, RE and VE mechanisms also play an important role in the superconducting state.³²

According to the observed macroscopic properties, Gd impurity possesses a well-defined spin and affects the superconducting properties in the way expected by the AG theory. Cerium impurity, however, shows the anomalies associated with the Kondo effect. In particular it seems very interesting to investigate microscopically by NMR the differences of the pair-breaking effects between the Gd and Ce impurities.

The relaxation rate R_s in a Kondo superconductor has been calculated numerically in the framework of the Müller–Hartmann–Zittartz depairing theory.³³ The theoretical temperature variation of R_s is expected to show very interesting behavior, corresponding to the reentrance behavior of superconductivity.

The host ^{27}Al nuclear spin–lattice relaxation in the normal and superconducting states of the $(\text{La}_{1-n}\text{Gd}_n)_3\text{Al}$ and $(\text{La}_{1-n}\text{Ce}_n)_3\text{Al}$ systems has been studied in detail.³⁴ The conclusions obtained are: (1) the impurity-induced relaxation rates play an important role in ^{27}Al relaxation and can be well interpreted by the LD mechanism for both the Gd and Ce doped systems; (2) the measured relaxation rates show large enhancement in the superconducting state. This seems to arise from the change of the impurity spin relaxation time. Quantitative analysis shows that the impurity spin dynamics is determined by the relaxation mechanism arising from the s–f exchange interaction between impurity spin and conduction electrons even in the superconducting state; and (3) in the vicinity of the transition temperature the observed temperature variation of T_1 seems to show a large discrepancy in comparison with the prediction of the impurity pair-breaking theory both in the Gd and Ce doped systems.

1 INTRODUCTION

The term 'adsorbed' implies concentrated at an interface. This article deals with the NMR of small molecules adsorbed, i.e. bound, to solid surfaces. (For a general introduction to adsorption and the properties of surfaces, see Adamson¹ or Somorjai.²) In addition to being of intrinsic scientific interest, adsorbed layers are of great practical importance in the areas of heterogeneous catalysis, separation science, and chromatography.

Molecules may bind to surfaces by any type of interaction, ranging from chemical bonding to van der Waals interaction. The case of chemical bonding is often called 'chemisorption', while the term 'physisorption' is sometimes used for weaker interactions. An adsorbed layer one molecule thick is called a 'monolayer' and thicker adsorbed deposits are called 'multilayers'. Clearly temperature is a major factor in determining the extent of adsorption, and appreciable adsorption will only be found when the interaction energy is greater in magnitude than kT .

NMR is the least sensitive of the common spectroscopic techniques, and thus the observation of adsorbed monolayers is dependent upon having a large amount of surface area in the NMR sample. The surfaces of highest specific area are those of activated carbon, and refractory oxides such as SiO_2 and Al_2O_3 . Because of their great importance as adsorbents, catalysts, and catalyst supports, the preparation of these has been much studied.^{3,4} These substances are readily prepared with specific surface areas of the order of hundreds of square meters per gram ($\text{m}^2 \text{g}^{-1}$). Their densities as powders are typically about 1 g cm^{-3} , so an NMR sample may contain hundreds of $\text{m}^2 \text{cm}^{-3}$. A monolayer of moderate sized molecules might contain $5 \mu\text{mol m}^{-2}$, so that the bulk concentration of an adsorbed monolayer can be of the order of 0.5 M. Such concentrations of sensitive high-abundance nuclei, e.g. ^1H , ^{19}F , and ^{31}P , can be observed in a single

scan with modern instrumentation. Those familiar with liquid NMR will find the effective sensitivity for adsorbed species to be considerably less, due to the much broader lines which arise for reasons noted below. None the less, high sensitivity nuclei are easily observed on such solids, and more difficult nuclei such as natural abundance ^{13}C can typically be observed in thousands or tens of thousands of scans. Often spin-lattice relaxation times for adsorbed molecules are appreciably shorter than for the same molecules in the liquid phase. This can make the signal averaging of large numbers of scans more feasible than might have been expected.

Another family of high area solids is the zeolites,⁵ crystals with internal pores of molecular size. The interior of these pores is equivalent to a high surface area, again typically of the order of hundreds of $\text{m}^2 \text{g}^{-1}$. Whether guest molecules inhabiting these pores can be said to be adsorbed is a matter of semantic convention. In this article the NMR of such guest molecules will be only briefly touched upon.

A large number of substances can be prepared in the $10 \text{ m}^2 \text{g}^{-1}$ range, and almost any solid can be prepared with $1 \text{ m}^2 \text{g}^{-1}$. Whether a high area preparation is stable with respect to loss of area by sintering depends mainly on the temperature. Typically the temperature must be kept below about one-half of the melting point to prevent substantial loss of area. A system of great practical interest is the supported metal catalyst.⁶ These catalysts consist of metal crystallites dispersed on a refractory oxide, such as silica or alumina. This technique permits a very high dispersion of the metal, with reduced tendency to sinter, and makes the most effective use of expensive platinum group metals. While the metal dispersion is extremely high, such catalysts typically contain a few per cent of metal by mass and have metal areas of 1 to $10 \text{ m}^2 \text{g}^{-1}$ of catalyst. Monolayers of high sensitivity nuclei are straightforward even at $1 \text{ m}^2 \text{g}^{-1}$; however, if one wishes to explore nuclei of low sensitivity, or small fractions of a monolayer, severe sensitivity problems eventually arise. One possible approach to this problem is to use the Curie law enhancement of NMR sensitivity at extremely low temperatures in the millikelvin range.⁷

In general, the preparation of high-area solids will result in an aggregate of randomly oriented crystallites. Some preparations, e.g. silica gels, will lack long-range order entirely. In a few favorable cases, high-area oriented samples can be prepared, e.g. in the case of lamellar clay particles by sedimentation.⁸

If one imagines a surface prepared by the sudden cleavage of a solid, it is evident that the surface may be viewed as a macroscopic radical with large numbers of 'dangling bonds', resulting from the disruption of the chemical bonds responsible for the integrity of the solid. Such a surface will be a very reactive entity and will be subject to structural rearrangement, which can lower its free energy, and to chemical reaction with its environment. Thus all metal surfaces (with the possible exception of Au) that have been in contact with the atmosphere will be covered by a layer of oxide. This layer may be a monolayer, or may be many layers thick. Similarly, oxide surfaces that have been exposed to the atmosphere normally have a monolayer of $-\text{OH}$ groups, resulting from their reaction with H_2O . This surface OH may be regarded either as the result of chemisorption of H_2O or as a normal constituent of oxide surface.

A 'clean' surface is one whose properties approximate the idealized cleaved crystal, at least as regards chemical

composition. (Many clean surfaces undergo rearrangement of their atoms to positions different from the bulk crystal.²) Clean surfaces are of much interest in fundamental surface science studies. In general, really clean surfaces are achieved only under ultrahigh vacuum conditions on areas of the order of 1 cm^2 ; adsorption on such surfaces is inaccessible to conventional NMR study at the present time. A possible exception to this statement is scattering experiments involving polarized atomic beams,^{9,10} which can yield nuclear relaxation data and possibly other NMR-like parameters. For the most part, however, present NMR studies involve surfaces that are at best partially clean. Thus, surface oxide can be removed from the noble metals by H_2 reduction, followed by thermal desorption of the resulting adsorbed H; surface OH can be largely removed from oxide surfaces by thermal treatment under vacuum. While not too attractive from the point of view of fundamental studies, the surfaces studied by NMR can easily be kept in a state similar to those used in practical applications for adsorption and catalysis, and NMR has substantial contributions to make to these fields.

The main features of the NMR of any sample will be determined by the mobility of the molecules studied. In this context, adsorbed layers are somewhat intermediate between liquid and solid samples. For many strongly chemisorbed samples, the adsorbed species are held in place by strong chemical bonds and are solids for NMR purposes. However, strong bonding to the surface does not necessarily imply localized bonding. For example, H atoms bind to most metal surfaces with an energy in excess of 200 kJ mol^{-1} , but in the case of the platinum group metals at room temperature they are mobile parallel to the surface on the NMR timescale, and are in some sense a two-dimensional fluid. Rotational motion of adsorbed molecules is also common, but the presence of the surface is likely to introduce greater anisotropy in this motion than would be observed in a liquid. Weakly bound physisorbed molecules are typically in rapid exchange with the gas phase, and average NMR properties will be observed. For high-area solids it will usually be the case that the adsorbed population is much larger than the gas-phase population, so that properties like chemical shifts will be dominated by those of the adsorbed phase, while the rapid exchange ensures that the motional properties of the layer appear liquid-like, both translationally and rotationally.

2 EARLY RESULTS

Not surprisingly, the first NMR studies of adsorbed species involved proton NMR^{11,12}. Since these predated high resolution solid state techniques, the possible experiments were broadline studies of immobile species, 'high-resolution' studies of mobile adsorbates, relaxation/linewidth measurements, and diffusion measurements by field gradient techniques. Examples of most of these exist from before 1960. For example, O'Reilly et al.¹³ observed that surface OH on silica and silica-alumina is chemically shifted with respect to liquid H_2O , and inferred from the temperature-independent Lorentzian lineshape that the OH forms a dilute randomly populated dipolar coupled system. Hickmott and Selwood¹⁴ studied the relaxation of water and several organics on various oxides, and showed the importance of surface paramagnetic species as relaxation agents. Fuschillo and Renton¹⁵ studied

the linewidth of methane on TiO_2 at low temperatures, and demonstrated the now well-known result that submonolayer amounts of physisorbed species do not become immobile until the temperature is well below the bulk freezing point.

In spite of these early successes, surface NMR in succeeding years proved somewhat disappointing. In general, very few chemical shifts proved to be measurable because of the large linewidths found for proton resonances. The sources of these linewidths were eventually realized to be rapid relaxation, especially by surface paramagnetic species, exchange with surface protons, heterogeneity of surface with respect to adsorption energetics, and inhomogeneous broadening from the nonzero magnetic susceptibility of irregular adsorbent particles; no proton linewidths less than 1 ppm were observed and much larger linewidths were common. Given the limited range of proton shifts, little of interest was shown regarding the structure and bonding of adsorbed molecules. Furthermore, with some notable exceptions,¹⁶ it turned out to be difficult to obtain information regarding molecular motion from relaxation studies. This was largely because of the difficulties of disentangling different relaxation processes, and the often dominant effect of paramagnetic surface species, in the presence of which correlation times may be determined more by electron relaxation than by adsorbate motions. The results of this early period are well summarized in the reviews by Packer¹⁷ and Pfeifer.¹⁸ Diffusion measurements, particularly in the context of guest molecules in zeolites, have recently been reviewed by Kärger et al.¹⁹

3 MULTINUCLEAR MAGNETIC RESONANCE

More possibilities were opened by the increasing availability of multinuclear and Fourier transform NMR equipment beginning in the 1970s. If, as it turns out, lines from adsorbed species will be at least a few ppm in width, chemical shifts should be observable for nuclei whose shift range is of the order of hundreds of ppm or more. An extreme example of this is the observation²⁰ of an 80 ppm shift for Ti^{4+} adsorbed from H_2O onto silica. In a more practical vein, the early 1970s saw the first natural abundance ^{13}C spectra of molecules in zeolites²¹ and physisorbed on silica²². Linewidths were a few ppm and it was possible to observe chemical shifts due, for example, to the hydrogen-bonding interaction of adsorbed acetone with surface hydroxyls. These works also demonstrated the possibility of measuring relaxation times separately for chemically different groups within a molecule. This could lead to simpler analysis of relaxation experiments for rigid molecules and the study of internal motions for others. In the early 1980s spectra were obtained for ^{15}N in a variety of molecules in zeolites²³ and adsorbed on SiO_2 ,²⁴ showing the advantages of studying the NMR of the atom which is the site of interaction between adsorbate and adsorbent. Relaxation studies of ^{17}O in H_2O on montmorillonite and kaolinite were performed.²⁵ These showed the desirability of measuring adsorbate correlation times in a system where strong quadrupolar interaction dominates the relaxation, and yielded surprisingly short correlation times for water in these systems, on the order of 10^{-11} s . Results to 1985 on multinuclear spectroscopy and relaxation measurements on adsorbed mobile molecules are comprehensively reviewed by Nagy, Engelhardt, and Michel.²⁶

4 HIGH-RESOLUTION SOLID STATE TECHNIQUES

The advent of high-resolution solid state NMR techniques in the 1960s and 1970s opened up new possibilities for the study of adsorbate systems. The most obvious of these is the identification of immobile chemisorbed species. The first use of these techniques by Kaplan et al.²⁷ was however a CP study of physisorbed benzene and toluene at low temperatures. Observation of an axially symmetric CSA powder pattern showed that benzene undergoes rapid rotation about the hexad axis, even at 77 K. Further experiments demonstrated that rapid cooling can trap molecules in a metastable isotropically rotating state at this temperature.

Magic angle spinning was first applied to surface problems by Stejskal et al.²⁸ in their study of CO₂ in zeolites. This showed that substantial line broadening which may arise from microscopic susceptibility variations in the adsorbate can be removed by MAS. Use of MAS in surface problems suffers from the conflicting requirements of atmospheric integrity, best achieved with sealed samples, and of excellent mechanical balance, which is likely to be degraded by the sealing process. This conflict was resolved in a semisatisfactory way in 1984.²⁹

The first use of multiple pulse line narrowing in surface studies was by Schreiber and Vaughan.³⁰ This permitted the measurement of the shielding anisotropy of surface protons on SiO₂; strong dipolar coupling to ²⁷Al prevented similar measurements on Al₂O₃. The combination of multiple pulse narrowing with MAS (CRAMPS), together with the use of higher magnetic fields, has recently been leading to growing success in the proton spectroscopy of adsorbed species.

5 ADSORBATES ON METALS

The resonance of hydrogen chemisorbed on platinum was first observed by Ito et al.³¹ Subsequently, the resonance of hydrogen has been observed on Cu, W, Ru, Rh, Pd, Os, Ir, and a few alloys, by these and other workers. (In the case of W, the cleanliness of the surface is questionable.) For all of the metals, large shifts are observed which cannot reasonably be chemical shifts and must therefore be Knight shifts. For Cu the shift is to high frequency, for the others to low frequency. With Ru–Cu bimetallic clusters³² the Knight shift of H on Ru decreases steadily as the Cu content is increased.

Platinum has been the most studied of these metals and it has been established that there is little difference between metallic powders and supported Pt catalysts. It has also been found that Knight shifts are smaller when the Pt particles are very small and when the adsorbed H covers a large fraction of the metal surface. As yet these trends have not received a satisfactory quantitative explanation in terms of the bonding between H and the metal surface. For all of the above metals the linewidth of the H resonance indicates that the hydrogen is mobile at room temperature. For those which have been studied to lower temperatures, motion generally ceases before liquid nitrogen temperature is reached.

¹³C NMR of CO chemisorbed on a metal was first studied by Duncan et al. on Rh.³³ Since then it has been studied on the remaining noble metals, and on bimetallic Pt–Rh particles. Much of this work is described in the reviews by Slichter³⁴ and Duncan.³⁵ On Ru and Rh an average shift is observed that corresponds to the known shifts of metal carbonyl complexes.

In static samples a broad powder pattern is observed with an anisotropy of some 400 ppm, corresponding to a linear carbonyl. On Rh, bridging carbonyl has also been observed. At room temperature, with the highest CO loadings, a narrow line appears from CO that is rotating isotropically on the NMR timescale. Thus the NMR of CO on Rh and Ru can be interpreted in terms of chemical shifts which are completely analogous to those observed in diamagnetic metal carbonyl complexes.

On the other hand, CO on supported Pt and Pd shows large high-frequency Knight shifts. Knight shifts are not observed for CO on colloidal platinum,³⁶ but it is not clear whether this is due to loss of metallic properties in the smaller particles or to interactions with the reagents used to stabilize the colloid. Supported Os and Ir show smaller high-frequency shifts and it is hard to be certain whether these are chemical or Knight shifts. Observations on Pt–Rh clusters³⁷ show that the Knight shift disappears above about 50% Rh, even though SEDOR measurements clearly show the presence of Pt in the surface layer of the particles.

The above results indicate that one must proceed with caution in interpreting the observed line positions of chemisorbed species on metals. For example, the metal (Rh) giving the largest Knight shift for adsorbed H gives no Knight shift for adsorbed CO. Thus in the absence of a reliable and comprehensive theory for Knight shifts of adsorbed species, every adsorption system must be examined carefully on its own merits.

6 ADSORPTION PROBES OF SURFACE SITES

The nature and concentration of specific types of site on solid surfaces has long been an area of interest, especially from the point of view of catalytic activity. These features can be probed spectroscopically by observing changes in the spectrum of a small molecule upon its binding to the surface. The archetypal example is the study of acid sites on oxide surfaces by IR spectroscopy of adsorbed amines;³⁸ pyridine, for example, gives distinct lines when physisorbed, protonated by a surface Brønsted acid, or coordinated to a surface Lewis acid.

This type of probing can obviously be done by NMR, which has the advantage that quantitative accuracy is in principle better. With IR spectroscopy it is generally difficult to be confident regarding the extinction coefficient of chemisorbed species, and there are often considerable uncertainties regarding path length and adsorbate concentration. Surface acids have thus been probed by direct proton NMR and by ¹³C, ¹⁵N, and ³¹P NMR of adsorbed amines and phosphines. Such attempts have been generally successful and are complementary to IR studies. Much of the work in this area has been reviewed by Freude.³⁹

Proton NMR cannot of course detect Lewis acids directly. For quantitative assessment of differing types of acid, ³¹P spectroscopy seems the most desirable. The high sensitivity of this nucleus permits spectra to be obtained in reasonable time periods by 90° pulse excitation, avoiding the need for cross polarization which may compromise quantitative accuracy. Most results have so far been obtained with trimethylphosphine as a probe; studies of a wider range of phosphorus bases seem likely in the future.

Solid surfaces may also contain basic sites; indeed, the same surface may simultaneously contain both strong acid and strong base sites. Probing these surfaces by NMR is less well developed, but a few results are available. For example, ^{13}C spectroscopy has been used to demonstrate, through the formation of surface bicarbonate from CO_2 , the unsurprising result that surface OH on MgO is basic.

7 SURFACE HYDROXYL GROUPS

As mentioned above, all oxides are covered with a layer of $-\text{OH}$ groups, which may in a formal sense be regarded as the result of water chemisorption on an ideal oxide surface. The surface chemistry of oxides in their normal state is largely determined by the properties of these hydroxyl groups. The properties of these hydroxyl groups vary from one oxide to another, and the same oxide may show differing types of $-\text{OH}$ groups, reflecting different exposed crystal planes, or different structural arrangements. Many of the classic NMR investigations^{13,30} have dealt with these groups, and the literature of studies by IR spectroscopy is particularly voluminous. Much of the IR literature and some of the NMR investigations have been reviewed by Morrow.⁴⁰ A recent review by Mastikhin et al.⁴¹ is devoted to NMR studies, particularly of recent results obtained through magic angle spinning.

8 CHEMICAL REACTION IN ADSORBED LAYERS

Adsorbed layers are the site of heterogeneous catalysis and hence reaction in these layers is a topic of immense scientific, technical, and economic interest. NMR studies of such reactions may proceed in two rather different ways. For reasonably rapid reactions of systems that are in equilibrium under NMR conditions, the familiar methods of shift, relaxation, and lineshape analysis may be employed, as in solution NMR. The possibilities for this type of study of adsorbed systems have been reviewed by Resing.⁴² On the other hand, slow reactions may easily be studied by recording NMR spectra as a function of time. A sealed NMR tube is in many ways an ideal contamination-free reactor. Reaction studies have been greatly advanced by CP MAS techniques, which permit the potential observation of a wide range of reaction products and intermediates.

For species reacting at a convenient rate at room temperature, e.g. the reaction of trimethyl phosphite with the silica surface,⁴³ straightforward MAS spectroscopy as a function of time can provide kinetic data for the surface reaction processes. For systems that are only reactive above room temperature, a 'quick and dirty' technique is to heat samples for controlled periods of time at the reaction temperature, and then cool to room temperature for NMR observation.⁴⁴ While this method provides useful insights, it suffers from uncontrolled conditions during the heating and cooling phases, together with uncertainties about desorption.

Clearly this type of study awaits the development of reliable high-temperature sealable MAS equipment, and recent progress has been made in this direction by Haw and coworkers.⁴⁵ Unfortunately, sealed-sample MAS is always

open to uncertainties arising from the possibility of desorption when the sample is heated above its preparation temperature. There seems no obvious way of combining the traditional catalytic flow reactor with MAS NMR. For the case of static samples, an NMR-compatible flow reactor has been designed by Reimer and co-workers.⁴⁶

9 STRUCTURE OF ADSORBED SPECIES

NMR of solids has the possibility of yielding direct structural information through measurement of dipolar interactions. Since the structures of chemisorbed species are in general not readily determined, this is a powerful possibility. The fundamental problem is that the motional state of observed species is not known a priori, and it will be unclear whether an observed dipolar coupling should be corrected for motional averaging. Thus, early observations of Pake doublets from adsorbed water⁸ (see also bibliography in Pfeifer¹⁸) generally gave splittings much too small to correspond to static H_2O molecules. These results were therefore not used to infer structural information, but were instead interpreted to give motional information based on the assumption of the known structure of isolated water molecules. In a system where significant structural changes have occurred due to chemical reaction, it seems necessary to demonstrate that observed dipole couplings are independent of temperature, or to give some other evidence for lack of motion, before inferring structural parameters.

Duncan and Vaughan⁴⁷ were among the first to use modern solid state methods to determine dipolar couplings in adsorbed layers. Their H-C dipolar modulation studies of adsorbed formic acid gave essentially the same coupling as observed in crystalline formates. A deviation from the expected bond length based on X-ray measurements of calcium formate was attributed to motion, even though the couplings in the adsorbed layer appeared temperature independent.

More recently, Slichter and co-workers³⁴ have applied spin echoes and SEDOR to measure homonuclear and heteronuclear dipole couplings in adsorbed layers, and to attempt to measure the bond length between adsorbate and surface. The latter endeavor is complicated by the possibility, with heavy nuclei such as ^{195}Pt , of indirect ('scalar') couplings of magnitudes comparable to the dipolar couplings.

In principle, dipolar couplings could be estimated from relaxation or NOE measurements. In practice, the often dominant effects of surface paramagnetic impurities, and the general anisotropy of motion in adsorbed layers, render this a complicated and unattractive prospect.

A less direct way of obtaining structural information from dipolar couplings is by the observation of multiple quantum coherence, from which the size of coupled spin aggregations may be inferred. This was first applied to surface problems by Slichter and co-workers,⁴⁸ and has recently been reviewed by Hwang and Gerstein.⁴⁹

10 MOTION IN ADSORBED LAYERS

As mentioned in the previous section, structural and motional determinations are a coupled problem pair. In general

the study of motions is simpler, because for many adsorbed systems the assumption of known structures in the adsorbed layer will be chemically tenable.

As indicated above, interpretation of relaxation is difficult in adsorbed systems. More reliable motional information is likely to be obtained by the observation of approximately local molecular properties, such as chemical shift anisotropies, dipolar splittings, and quadrupolar couplings. Thus the first CP study²⁷ of an adsorbed layer revealed an axially symmetric CSA powder pattern for physisorbed benzene at 77 K. This indicated rapid rotation about the sixfold axis at a temperature well below that at which such rotation occurs in the solid.

Subsequently, Resing and co-workers used analysis of CSA powder patterns to determine the motions of various adsorbed species, such as anchored phenyl groups.⁵⁰ Sindorf and Maciel⁵¹ used cross polarization rates as an indicator of average C–H dipolar coupling to study the dynamics of long alkyl chains bound to silica surfaces. Yannoni et al.⁵² observed C–C dipolar splittings in doubly-labeled benzene to study its structure and motions on a Pt–Al₂O₃ catalyst. The use of deuterium quadrupolar powder patterns to study motions in adsorbed phases is exemplified by the elegant studies of Luz et al.⁵³ on methyl amines sorbed in zeolites.

1 INTRODUCTION

Chemical exchange, i.e. the transfer of atoms, molecules or molecular groups between two or more different environments or regions, is a phenomenon encountered frequently in studies by NMR of a wide variety of chemical, physical and biological systems. Different environments are usually revealed in NMR experiments through distinct resonance frequencies, spin–spin coupling constants, or relaxation times characteristic of the regions between which chemical exchange takes place. The types of atomic or molecular motion most often investigated on metal surfaces include surface diffusion, adsorption and desorption, exchange between different surface sites or different types of adsorbed species, molecular reorientation, and reorientation of molecular groups.

Because NMR requires at least ca. 10^{18} spins at the surface to be able to detect a signal, single crystal surfaces cannot be studied (10^{15} spins). However, introducing the metal in the form of small particles with diameters in the order of nanometers into porous materials, provides a sufficiently high number of surface sites for adsorption to be studied by NMR. These support materials are mostly oxide compounds like silica, alumina, titania, or zeolites with high internal surfaces of several hundred square meters. At the same time, highly dispersed supported metals, e.g. group VIII elements like ruthenium, rhodium, palladium, osmium, iridium, and platinum, are very often of interest in basic and applied research in catalysis (see also *Supported Metal Catalysts*, and *Adsorbed Species: Spectroscopy and Dynamics*).

Several NMR techniques are available to study exchange phenomena of adsorbed species. Spin–lattice relaxation¹ measurements are useful if chemical exchange dominates as a source for relaxation, or can be separated from other relaxation mechanisms, e.g. relaxation via the conduction electrons of the metal, called Korringa relaxation (see *Electron–Nuclear Hyperfine Interactions*). To be investigated by relaxation measurements, the characteristic time constants of exchange τ_{ex} have to be in the order of 10^{-9} s for spin–lattice relaxation in the laboratory frame to 10^{-5} s for spin–lattice relaxation in the rotating frame.¹ For a review of the relaxation method used to study the dynamics on surfaces we refer the reader to the literature.^{2–4} The analysis of lineshapes or resonance shifts

obtained by conventional NMR techniques are sensitive in the dynamic range of $10^{-6} \leq \tau_{\text{ex}} \leq 10^{-3}$ s. Spin labeling methods extend this range up to more than 10^{-1} s. Two-dimensional NMR techniques, applicable in approximately the same slow dynamic range, are most effective if the exchanging species exhibit separate NMR peaks or if well-defined lineshapes due to anisotropic interactions can be observed.⁵

In the present article the theoretical basis necessary to understand the evolution of nuclear spin magnetization influenced by chemical exchange is outlined briefly. The reader is introduced to spin-labeling and two-dimensional (2D) NMR techniques, which are frequently used to monitor exchange. Finally, experimental examples regarding chemical exchange on metal surfaces are discussed.

2 THEORY OF MAGNETIZATION EXCHANGE

In the following it is assumed that the spatial motion of molecules or atoms can be described classically. If all spin interactions are secular with respect to the Zeeman interaction, i.e., the corresponding interaction Hamiltonians commute with the Zeeman Hamiltonian, then each spin can be considered as being subjected to a local field arising from the environment, superimposed on the external static field. Chemical exchange has the effect of causing random fluctuations of the local field. For example, a nuclear spin situated in a molecule or atom, which jumps randomly between two regions on a surface, such that each region gives rise to a different isotropic resonance shift, experiences a random modulation of its resonance frequency. The influence of such frequency fluctuations upon the NMR lineshape was first treated by Hahn, Maxwell, Gutowsky, McCall, and Slichter.⁶

If the spin Hamiltonian contains nonsecular terms, arising, for example, from J couplings observed commonly in liquids, a quantum-mechanical treatment (spin density matrix formalism) is required.⁷ Splittings due to J couplings are often difficult to detect in NMR studies of adsorbates on metal surfaces because of insufficient spectral resolution, caused by the heterogeneity of the system, leading to distributions of isotropic chemical or Knight shifts, and/or the presence of ‘solid-like’ spin interactions much stronger than J coupling, like chemical shift anisotropy (see *Internal Spin Interactions and Rotations in Solids*) and paramagnetic shifts.

We confine ourselves here exclusively to the case of secular spin interactions, leading to a classical probabilistic model for the magnetization exchange originating from chemical exchange processes. The probabilistic model is commonly represented by a stationary Markov process,^{8,9} allowing the derivation of equations of motion for the nuclear spin magnetization in the form of generalized Bloch equations.^{9–11} The evolution of longitudinal and transversal magnetization components for all regions, between which exchange takes place, are given as a system of coupled differential equations with rate coefficients describing the magnetization exchange process. Solving these equations is a standard problem of analysis and matrix algebra (see Ernst et al.¹¹ and Jeener et al.¹³) and enables explicit calculation of NMR lineshapes.

Figure 1 illustrates the principal effects on the NMR lineshapes originating from magnetization exchange between two regions or sites. Regions A and B, populated by N_A and N_B spins, respectively, are characterized by distinct resonance

Figure 1 (a) NMR lineshape versus $\delta\omega\tau_{\text{ex}}$ for symmetric two-site exchange ($N_A = N_B$). (b) Variation of the resonance frequency in the fast exchange limit as a function of $N_A:N_B$

frequencies ω_A and ω_B , $\delta\omega = \omega_B - \omega_A$. This difference of resonance frequencies may be caused by different isotropic chemical or Knight shifts. In the slow exchange limit, $\delta\omega\tau_{\text{ex}} \gg 1$, where τ_{ex} is a characteristic time constant for the exchange process, two separate lines appear in the NMR spectrum [Figure 1(a)], which become broadened with decreasing $\delta\omega\tau_{\text{ex}}$, and coalesce to a single broad line at $\delta\omega\tau_{\text{ex}} \approx 1$. With $\delta\omega\tau_{\text{ex}}$ decreasing further, only one single ‘exchange-averaged’ narrow line is observed (fast exchange limit, $\delta\omega\tau_{\text{ex}} \ll 1$). The spectra in Figure 1(b) were calculated for the fast exchange limit varying the ratio $N_A:N_B$ of spin numbers in regions A and B, leading to a variation in the resonance frequency of the exchange averaged resonance line as well as to a broadening for values of $N_A:N_B$ near unity. The dependence of the resonance shift δ on N_A and N_B can be expressed for the fast exchange limit as the weighted average:

$$\delta = \frac{N_A}{N_A + N_B} \delta_A + \frac{N_B}{N_A + N_B} \delta_B \quad (1)$$

of the individual resonance shifts δ_A and δ_B . The mathematical formalism to calculate the above lineshapes is still applicable if anisotropic interactions, to be described by interaction tensors, e.g. chemical shift anisotropy, are present. However, because of the random spatial orientations of the principal tensor axes in a powder sample, the resulting orientation dependence of the resonance frequencies has to be taken into account to obtain the lineshape.¹⁰

3 ADVANCED NMR TECHNIQUES TO MONITOR EXCHANGE

As shown above, no significant changes of the one-dimensional NMR lineshapes or frequencies occur in the slow exchange limit. More advanced NMR techniques are available to detect such slow exchange processes.

3.1 Spin Labeling by Selective Excitation

The idea of spin labeling is based on the fact that the actual chemical exchange process, being in thermal equilibrium, causes an exchange of spin magnetization.¹² The latter is initially prepared by irradiation of rf pulses to be in nonequilibrium. The irradiation of an rf pulse, or a sequence of rf pulses affects only spins resonating within the spectral excitation window defined by the Fourier transform of the pulse sequence [Figure 2(a) and (b)]. Although this Fourier picture is only an approximation when selective saturation or inversion is considered,¹² it is a useful qualitative description. Denoting the length of a single rf pulse or the total duration of a pulse sequence by τ_p , the excitation width in the frequency domain is proportional to $1/\tau_p$, with the rf carrier frequency in the center of the excitation window. The irradiation of either a long pulse of low rf power or a sequence of strong, but very short pulses, as indicated in Figure 2(a), allows selective excitation of spins. The pulse sequence can be adjusted to act in total like a 90° pulse (selective saturation) or a 180° pulse [selective inversion, illustrated in Figure 2(c)]. Therefore, spins within the spectral window can be labeled, for example, by inversion of their magnetization, while spins which resonate outside the window remain unaffected. If a pulse sequence is used, excitation sidebands also occur [Figure 2(b)]. During a subsequent time interval τ_m [Figure 2(a)] the spin system is allowed to undergo free time evolution. The NMR signal is detected finally by a short (nonselective) 90° pulse. Selective excitation (saturation or inversion) of a narrow frequency band within a broad NMR line, for example, caused by chemical shift anisotropy, is called ‘spectral hole-burning’. If chemical exchange is present, the labeled spins may change their resonance frequencies resulting in a redistribution of spin

Figure 2 Spin labeling by selective excitation: (a) pulse sequence, (b) Fourier transformation of the train of equidistant pulses, and (c) NMR spectrum showing a selectively inverted line

magnetization toward spectral regions outside of the selected window. The recovery of the spectral hole, or of the intensity of an inverted single resonance line, can be measured as a function of the recovery time τ_m to reveal the kinetics of a chemical exchange process.

Magnetization recovery is also caused by spin–lattice relaxation of the spin magnetization. Only exchange processes with a characteristic time τ_{ex} shorter than the spin–lattice relaxation time T_1 can be observed. Spin-labeling becomes ineffective if the chemical exchange process is faster than the spin-labeling process itself (characteristic time constant τ_p). Thus accessible by spin-labeling techniques are exchange processes within a timescale $\tau_p < \tau_{ex} < T_1$.

3.2 Two-Dimensional Exchange NMR

Two-dimensional exchange NMR techniques¹³ are based on the idea of measuring the frequency of spin magnetization components at two different times during the NMR experiment. After the initial preparation period, which consists of a waiting period to allow equilibration of the longitudinal magnetization and irradiating the first $\pi/2$ pulse, transversal magnetizations are present, oscillating with frequencies ω_A and ω_B during the time t_1 [evolution period, Figure 3(a)] corresponding to spins located in regions A and B. A second $\pi/2$ pulse converts the magnetization present at time t_1 into longitudinal magnetization. During the mixing time τ_m (usually much longer than the time t_1) slow chemical exchange leads to a random modulation of the precession frequencies of the two magnetization components M_{zA} and M_{zB} . Spins which were resonating at ω_A at the end of the period t_1 may resonate at either ω_A or ω_B at the end of the mixing period τ_m (and vice versa). The NMR signal is detected after the final $\pi/2$ pulse during the time period t_2 . Repeating the experiment by incrementing the time t_1 in small steps, yields a two-dimensional time-domain interferogram which after 2D Fourier transformation¹¹ with respect to t_1 and t_2 gives the 2D NMR spectrum $S(\omega_1, \omega_2)$. If exchange occurs between A and B, cross peaks are observed, labeled A $\rightarrow$ B and B $\rightarrow$ A in Figure 3(b), in addition to main peaks A and B located along the principal diagonal.¹⁴

4 CHEMICAL EXCHANGE OF ADSORBED SPECIES ON METAL SURFACES: EXAMPLES

Chemical exchange phenomena at or near metal surfaces observed by NMR encompass a wide dynamical range extending from the fast exchange limit ($\tau_{ex} < 10^{-5}$ s) to extremely slow processes ($\tau_{ex} > 1$ s). The details of the chemical exchange processes might be quite different, originating, for example, from adsorption or desorption, exchange between different surface sites, exchange between different populations of adsorbed species or surface diffusion.¹⁵

4.1 Exchange Dynamics of CO Adsorbed on Metals

Carbon-13 spin labeling techniques have been applied by Duncan, et al.¹⁶ to elucidate in detail surface diffusion of

Figure 3 (a) Basic 2D NMR pulse sequence to monitor exchange. (b) Schematic representation of a 2D NMR spectrum for exchange between two sites A and B

CO and slow exchange between different carbonyl species adsorbed on rhodium. Molitor and Apple¹⁷ performed ^{13}C NMR powder lineshape calculations for reorientating dicarbonyl groups bonded to rhodium. Surface diffusion of CO chemisorbed on palladium has been investigated by means of ^{13}C relaxation measurements and lineshape analysis.¹⁸

4.2 Fast Exchange of Hydrogen on Metal Surfaces

Proton NMR peaks of hydrogen interacting with metal surfaces are commonly shifted to lower frequency (i.e. upfield) due to the Knight shift interaction and reveal relatively small linewidths, especially at elevated external H_2 pressures and temperatures above room temperature, indicating high intrinsic mobility. Variations of the resonance frequency of ^1H NMR peaks, attributed to hydrogen on the metal surface, versus pressure (i.e. changing the number of hydrogen atoms or molecules on the surface) may be caused by at least two different mechanisms: (i) fast exchange between surface environments with different Knight shifts [as illustrated in Figure 1(b)]; and (ii) by a variation of the Knight shift interaction itself, because the latter may be a function of the surface coverage. As pointed out above, fast exchange between two regions leads to an averaged NMR line representing hydrogen in both regions. Variation of the resonance shift

Figure 4 ^1H NMR resonance shift δ for hydrogen adsorbed on ruthenium–copper bimetallic particles and fraction X_{Ru} of surface ruthenium as a function of the copper content

with pressure, or coverage, has been observed quite frequently by ^1H NMR¹⁹ or ^2H NMR²⁰ for hydrogen adsorbed on various metals like platinum, rhodium, and ruthenium (see also refs. 18–20 and 23–24 given in Wu et al.¹⁹). The resonance shift variation of hydrogen due to fast exchange between different surfaced regions has been used to monitor the surface composition of bimetallic particles.²¹ In this case hydrogen atoms are rapidly exchanging between sites on the bimetallic particle surface, composed of sites with different Knight shifts for adsorbed hydrogen. As shown in Figure 4, on particles consisting of pure ruthenium, hydrogen resonates at -62 ppm [to low frequency relative to tetramethylsilane (TMS)]. Increasing the total copper content of the sample leads to a systematic decrease of the ^1H NMR resonance shift δ , approaching asymptotically the value of -49 ppm for a copper content near 80 at%. This shift value is regarded as the resonance shift for hydrogen adsorbed on copper sites of ruthenium–copper bimetallic particles. Applying equation (1) inserting $\delta_{\text{Cu}} = -49$ ppm and $\delta_{\text{Ru}} = -62$ ppm, the fraction $X_{\text{Ru}} = N_{\text{Ru}}/(N_{\text{Ru}} + N_{\text{Cu}})$ of ruthenium atoms exposed at the particle surface can be determined (see Figure 4). Therefore, in this example the ^1H NMR resonance shift provides a sensitive measure for the composition of the surface.

4.3 Slow Exchange Between Different Hydrogen Populations on the Metal Surface

Figure 5(a) shows an in situ ^1H NMR spectrum of silica supported ruthenium, obtained at $T = 400$ K and at an external H_2 pressure of 300 Torr.²² Two distinct resonance lines (denoted as α and β) are observed, originating from two different hydrogen species, characterized by different heats of adsorption. The 2D exchange NMR spectrum [Figure 5(b)] was obtained by the pulse sequence illustrated in Figure 3(a). The cross peaks reveal a slow exchange process within the timescale of the experiment, given by the mixing time $\tau_{\text{mix}} = 2$ ms, occurring between α and β hydrogen, but there is no exchange within this timescale between the α or β species and the hydrogen residing on the silica support. Spin

Figure 5 (a) Conventional ^1H NMR spectrum of silica supported ruthenium. (b) 2D exchange NMR spectrum at $T = 400$ K and external H_2 pressure $p = 300$ Torr

labeling of one of the two spin species, α or β , by selective excitation (Figure 2) allows the determination of the average time constant, $\tau_{\text{ex}} = 700 \mu\text{s}$, for the magnetization exchange between α and β hydrogen.

1 INTRODUCTION

The unique properties of diamond, such as its high thermal conductivity, mechanical characteristics, optical transparency, and semiconductor characteristics, make it an attractive material for many applications.¹ Synthetic diamond powders and single crystals were first made in high-pressure/high-temperature (HPHT) processes in the 1950s. More recently, diamond films have been grown at technologically significant rates using a variety of subatmospheric chemical vapor deposition (CVD) processes. The primary distinction between these CVD techniques is the method by which energy is introduced in order to dissociate and excite the gas phase reactants.² Activation of the gas phase diamond precursors has been achieved by direct current (DC) plasmas, microwave (MW) plasmas, hot filaments, and combustion flames. Although significant variations in growth rates exist between these methods, all seem capable of producing highly faceted polycrystalline films with little evidence of nondiamond carbon and with low hydrogen concentrations (<0.5 at.%). Thus, diamond films are distinctly different from diamond-like carbon (DLC) films, which are amorphous, can have a significant fraction of sp²-bonded carbon, and can have >30 at.% hydrogen.³

The deposition of diamond at low pressures, where it is metastable, appears to involve a kinetic competition between the growth and etching of various forms of carbon ranging from diamond (tetrahedral sp³ bonded), through amorphous sp³ and sp² configurations, to graphitic carbon (sp²). The range of successful reactant compositions is surprisingly similar for the various types of CVD processes.³ Diamond films are most commonly deposited from a dilute mixture of hydrocarbons (0.5–2.0%), such as methane or acetylene, in hydrogen. However, studies of carbon sources containing oxygen (e.g. acetone, ethanol, and carbon monoxide) and halogens (fluorine and chlorine) have also shown promising results. The energy introduced into the gas phase produces molecular fragments and excited species which react on the surface of the substrate which is generally maintained at 800–1000 °C.

The hydrogen which is often predominant in the gas phase has been proposed both to stabilize the growing diamond surface and to etch graphitic carbon.^{1–3} The electrical

resistivity of diamond has been proposed to depend on hydrogen incorporation.⁴ Also, increased hydrogen contents correlate with decreased transparency in the 8–10 μm wavelength region, degrading the performance of diamond as an infrared window.^{5,6} Thus, the location and distribution of hydrogen can provide insight into diamond deposition chemistry and structure–property relationships in these films.

The commercial exploitation of CVD diamond requires consistent high-quality production, and defect-free films and coatings. While many techniques have been used to evaluate diamond film quality, most provide only qualitative information on which to evaluate differences in deposition conditions. Hydrogen is particularly difficult to measure in solid thin films.⁷ The primary advantage of NMR measurements is their quantitative nature. In addition, the low-energy radiofrequency irradiation used in NMR is unlikely to result in chemical alteration of the diamond samples, unlike some higher-energy spectroscopic techniques. To date, diamond has been studied by ¹H,^{5–10} ¹³C,^{11–22} and ¹⁹F²³ NMR, often providing information which is unattainable by other techniques.

For static NMR measurements, one or more sections of a free-standing diamond film, generally >10 μm thick, may be inserted directly into the NMR sample coil.⁵ By not using a conventional NMR tube or rotor, a potential source of background signal is eliminated.⁷ This is a particularly important consideration when studying thin films, since sample sizes are generally limited and the concentration of NMR active nuclei is often low. In addition, the macroscopic integrity of the film is maintained. Similarly, laser-cut disks of free-standing diamond can be stacked into MAS rotors if examination of intact films is desired.²² Alternatively, powder, formed by crushing a film or removing a very thin film from its substrate, can be packed into an NMR tube or rotor.

In some instances, NMR spectra of films can also be acquired without removing their growth substrates.¹⁷ For such experiments, the substrate must be nonmagnetic, have a low conductivity, have a similar magnetic susceptibility to the diamond film, and must contribute little background signal for the nuclei to be observed. These conditions can be met by using high-resistivity silicon wafers manufactured by the float zone process. The use of thin wafers (≤75 mm in thickness) maximizes the number of film sections which can be inserted into the NMR coil.

2 CARBON-13

The isotropic chemical shift can resolve sp²- from sp³-bonded carbon. Bulk diamond is characterized by a single resonance at 36 ± 2 ppm¹¹ relative to tetramethylsilane (Figure 1).¹³ The sp² carbon peak generally appears between 120 and 200 ppm, with the lower values observed for amorphous carbon films,⁴ while soot gives a peak centered at 189 ppm.¹⁸ The ratio of sp²/sp³ bonded carbon is quantitatively determined from the ratio of the integrated area under the peaks corresponding to these respective environments and has been experimentally demonstrated for diamond powder and soot mixture of known weight fraction.¹⁸

The linewidth of the sp³ peak of natural diamond in the static ¹³C spectra is dominated by homonuclear dipole

Figure 1 Static direct polarization (DP) ^{13}C NMR at 67.9 MHz of 3 carats of gemstone natural diamonds. The $\Delta\nu_{1/2}$ of 250 Hz includes 50 Hz added Lorentzian broadening. (Adapted from Henrichs et al.)¹³

broadening. The second moment of this interaction can be calculated via the Van Vleck equation:^{12,25}

$$M_2 = \frac{3}{4} \gamma^4 \hbar^2 I(I+1) f \sum_k \frac{(1 - 3 \cos^2 \theta_{jk})^2}{r_{jk}^6} \quad (1)$$

where r_{jk} is the distance between two sites, and f is the fraction of these sites randomly occupied by the NMR-active nuclei of interest. The dependence on θ_{jk} , the angle the intersite vector makes with the external magnetic field, causes M_2 for a powdered sample to differ from that of a single crystal having an identical chemical structure. When active nuclear spins are dilute ($f < 0.01$), a truncated Lorentzian lineshape results, with a full width given by

$$\Delta\nu_{1/2} = \frac{\pi}{\sqrt{3}} \left(\frac{M_2^2}{M_4} \right)^{1/2} (M_2)^{1/2} \quad (2)$$

Note that the point chosen for truncation influences the ratio M_2^2/M_4 . For higher spin densities, a Gaussian lineshape is observed, with a linewidth of

$$\Delta\nu_{1/2} = 2.35(M_2)^{1/2} \quad (3)$$

These linewidths are independent of the applied magnetic field; hence, chemical shift resolution can be improved at higher fields.

Using equation (1) for a diamond lattice with a natural abundance of ^{13}C ($f = 0.011$) yields $M_2 = 0.037 \text{ kHz}^2$ for a single crystal oriented with its (014) axis parallel to the external magnetic field, which compares favorably with the measured value of $M_2 = 0.041 \text{ kHz}^2$, confirming that homonuclear dipolar interactions are the dominant source of broadening in this environment.¹² The corresponding observed lineshape is a truncated Lorentzian with $\Delta\nu_{1/2} = 200 \text{ Hz}$,¹² similar to that shown in Figure 1.¹³

In materials with high hydrogen concentrations, like polymers and DLC films,²⁴ CP can be used to enhance the ^{13}C spectrum. However, variations in CP dynamics can cause the quantitative character of the NMR experiment to be lost. The low hydrogen concentrations found in polycrystalline diamond films make CP difficult, although achievable.¹⁴ In the vicinity of hydrogen, where CP is most efficient, only sp^3 -bonded carbon nuclei were detected. Also, because ^1H - ^{13}C heteronuclear dipole couplings are generally negligible in diamond films, proton decoupling is often not required. Direct polarization

(DP) ^{13}C NMR, while requiring larger samples, is a means of obtaining quantitative sp^2/sp^3 ratios. Typically, $>5 \times 10^{18}$ ^{13}C nuclei are required,¹⁸ corresponding to $\sim 10 \text{ mg}$ of a natural abundance diamond, which is equivalent to a $10 \mu\text{m}$ thick film over an area of 2.8 cm^2 .

In samples which are free of paramagnetic defects, DP NMR experiments are quantitative in that each ^{13}C nucleus gives rise to the same integrated signal intensity, regardless of its bonding environment. In samples containing paramagnetic impurities, a small fraction of nuclei in close proximity to such defects will remain undetected as a result of extreme line broadening due to interaction with the unpaired electron of the paramagnetic impurity.^{12,13} However, only a small fraction of nuclei should be affected by the paramagnetic densities (10^{17} – 10^{18} g^{-1}) in diamond films.^{20,21} This assumption can be verified by comparing the experimental signal intensity to the expected intensity based on mass and ^{13}C enrichment in the sample and response of the spectrometer to standards of known ^{13}C content. Fortunately, these experiments show that the effects of broadening by paramagnetic centers are often below the NMR detection limit.¹⁸ For quantitative measurements, it is also important to insure that a sufficient delay ($\geq 5T_1$) is used between signal acquisitions.

Isotopic enrichment can be used to decrease sample size requirements.^{17–19,21} The spin–lattice relaxation rate will also increase as a result of enhanced spin diffusion in the ^{13}C -enriched samples. Both factors lead to increased sensitivity and/or decreased acquisition times. The concentration of ^{13}C in the solid film can be determined via the second moment of the homonuclear dipole couplings [see equation (1)]. The degree of enrichment determined in this manner is in excellent agreement with measurements of the isotopic shift of the diamond one-phonon absorption in the Raman spectra.¹⁹ However, enrichments $>25\%$ will limit spectral resolution of sp^2 versus sp^3 carbon due to homonuclear dipolar line broadening [see equation (1)]. Resolution may be restored by MAS at speeds greater than the ^{13}C – ^{13}C homonuclear dipole broadening in hertz, i.e. spinning frequencies of more than 4 kHz.

Selective isotopic labeling can be used to gain insight into the chemistry of diamond formation when more than one chemically distinct carbon is present in the gas phase reactant mixture.^{17–19} For instance, films have been grown using acetone, selectively ^{13}C labeled at either the methyl or carbonyl site, as the reactive carbon source. Measuring the resulting ^{13}C concentration in a pair of otherwise identical films determines the relative efficiency at which the methyl and carbonyl sites from the selectively labeled acetone are incorporated into diamond. When such experiments are carried out in a hot filament reactor, both labels are incorporated equally when a tantalum filament is used.^{17,18} In contrast, diamond deposits preferentially from the methyl site when a rhenium filament is employed.¹⁹ However, some growth from the carbonyl site is still observed when rhenium is used. Such experiments demonstrate the importance of heterogeneous chemistry at the filament in this type of CVD reactor.

In polycrystalline CVD films, the diamond peak is nearly symmetric, revealing little CSA, as expected for a tetrahedrally symmetric bonding environment. For static spectra, the $\Delta\nu_{1/2}$ ranges from 310 to 500 Hz in unenriched films,^{18,21} indicating broadening in addition to homonuclear dipole interactions. MAS at sufficient speeds can average broadening due

Figure 2 Static DP ^{13}C NMR at 75 MHz of two CVD diamond films, enriched to 22% ^{13}C . (a) The highly faceted film shows only the 36 ppm resonance characteristic of sp^3 bonding environments. (b) A broader sp^3 peak and a second peak at ~ 120 ppm due to sp^2 carbon are seen in the second film, which also has much poorer morphology. (Adapted from McNamara et al.)¹⁸

to dipolar interactions, CSA, and variations in magnetic susceptibility. Thus, any remaining broadening can be attributed to a wider distribution of bond angles and lengths in the film. A highly faceted hot filament film on its substrate, with 22% ^{13}C enrichment, produces a symmetric Gaussian lineshape with $\Delta\nu_{1/2} \sim 3$ kHz [Figure 2(a)],¹⁷ in reasonable agreement with equations (1) and (3). Upon crushing this sample and performing MAS, the $\Delta\nu_{1/2}$ was reduced to 150 Hz. Variations in MAS $\Delta\nu_{1/2}$ from 6 to 55 Hz in natural abundance samples have been linearly correlated to increases in Raman one-phonon linewidth, which is also associated with increasing disorder of the diamond phase.²¹

Asymmetry in the sp^2 peak is expected as a result of CSA and/or bond angle disorder. Unfortunately, sp^2 -bonded carbon in visibly faceted films produced via hot filament, DC arc jet, or MW plasma CVD is generally below the ^{13}C NMR detection limit.¹⁸ An sp^2 resonance has been observed in a film of poor morphology and no detectable diamond one-phonon Raman absorption.¹⁷ This film was prepared under identical conditions to the highly faceted hot filament film discussed above [Figure 2(a)], with the sole exception that the C/H ratio in gas feed was increased, resulting in poorer film quality. The static NMR spectra of this 22% enriched film, intact on its substrate, resolves both broad sp^2 and sp^3 peaks at ~ 120 and ~ 38 ppm, respectively [Figure 2(b)]. The ratio of the areas of these two peaks gives a quantitative sp^2/sp^3 ratio of 0.11 ± 0.2 , indicating that $\sim 10\%$ of the carbon in this film is bonded in an sp^2 configuration. The MAS linewidth of the sp^3 peak narrows to only $\Delta\nu_{1/2} = 690$ Hz, indicating some disorder in the

sp^3 environment, while the lineshape of the sp^2 peak remains relatively unaltered, indicating a high degree of disorder in this phase.

Quantitative sp^2/sp^3 ratios measured by solid state ^{13}C NMR have been compared with qualitative results of Raman spectroscopy,¹⁸ one of the most widely used techniques for characterizing diamond thin films. Raman is sensitive to both the sp^2 and sp^3 bonding environments but is difficult to quantify since the scattering efficiency of sp^2 -bonded carbon differs from sp^3 -bonded material, and each may vary from film to film. In addition, the sp^2 - and sp^3 -bonded carbons may have different absorptivities, which can lead to nonuniform sampling as a function of depth in the film.

As expected, Raman spectroscopy is extremely sensitive to sp^2 -bonded carbon, identifying small amounts below the detection limit of the NMR spectrometer. Comparison of the two techniques, however, indicates that Raman spectroscopy may be so sensitive to sp^2 -bonded carbon that sp^3 -bonded carbon in films containing as much as 90% sp^3 -bonded material may remain undetected. This is undesirable when new deposition conditions are being explored, since conditions which yield a majority of sp^3 -bonded sites can be overlooked by the Raman analysis.

These two techniques also differ in that NMR spectroscopy is sensitive to short-range order, while Raman spectroscopy probes order over a longer range. NMR provides only information averaged over the entire sample volume and requires relatively large samples and long acquisition times. Raman spectroscopy has the advantage of giving fast, spatially resolved information. A combination of the two techniques is desirable for obtaining reliable information for all types of diamond.

Another method for enhancing the sensitivity of NMR for characterizing diamond films is DNP.^{20,21} The work on diamond films builds upon earlier DNP investigations of natural and HPHT diamond.^{15,16} Polarization from paramagnetic defects is transferred to the nuclear spin reservoir by simultaneous irradiation at the electron spin and ^{13}C Larmor frequencies. The ^{13}C nuclei close to paramagnetic sites polarize most quickly. Thus, the local composition can be investigated as a function of distance from the paramagnetic sites using variable contact time experiments. Often DNP is combined with MAS in order to suppress spin diffusion.¹⁶ When DNP is combined with CP from ^1H nuclei, hydrogenated regions can be selectively probed.^{20,21}

The 1.4 T ^{13}C DNP MAS spectra of CVD diamond have been published for an 83 mg natural abundance sample (Figure 3) and for two $\sim 14\%$ enriched samples of 20 and 29 mg, respectively. Although acquisition time is reduced by using DNP, this advantage is somewhat offset by the use of high magnetic fields by the more commonly available conventional NMR spectrometers.²⁰ The ^{13}C DP MAS spectra of the enriched samples was also acquired on a conventional NMR spectrometer, using a 14 T magnet.²¹ In addition, the static DP spectra of the same three samples had previously been reported using a 7 T NMR spectrometer.¹⁸

The main feature of the three DNP MAS spectra is a characteristic line at 36 ppm (Figure 3), which is also observed for bulk diamond. In some cases, a small, broad shoulder on this peak at ~ 45 ppm has been identified as hydrogenated sp^3 -bonded carbon through its response to both ^1H - ^{13}C variable CP contact times and dipolar dephasing experiments.²¹ This

Figure 3 Static DP-DNP ^{13}C NMR at 15 MHz of natural isotopic abundance CVD diamond film, showing only the characteristic peak for diamond. (Adapted from Lock and Maciel²⁰)

position falls in the calculated chemical shift range of 25–54 ppm for saturated hydrocarbons with an underlying diamond skeleton. These calculations start with adamantane and progress through fully hydrogen-terminated diamond surfaces, and are compared to experimental measurements where possible.²¹ A sharp peak centered at 28 ppm, observed only in DP MAS experiments may indicate freely rotating methyl groups. Only when intermediate ^1H – ^{13}C CP contact times were employed with the DNP MAS experiments was a broad, weak resonance observed at ~ 140 ppm in one of the enriched films. This peak was not observed using DNP MAS in the absence of CP, suggesting this sp^2 -bonded carbon is localized near hydrogenated sites. Unfortunately, the sp^2/sp^3 ratio could not be quantified because the polarization dynamics from both the paramagnetic defects and the proton reservoir are not well known in these samples.

3 PROTON NMR

Figure 4 shows representative ^1H NMR spectra, taken at a Larmor frequency of 270 MHz.^{5–10} Approximately 1500 signal transients were acquired at a repetition rate of 5 s, in accordance with typical proton T_1 s of less than 1 s in these samples, which contained $>10^{17}$ total proton spins. By not using an NMR sample tube and purging the NMR probe with dry nitrogen, the need for background subtraction was eliminated. Integrating such spectra yields concentrations ranging from <0.017 to ~ 0.5 at.% hydrogen, depending upon the exact film growth conditions used. The concentrations of hydrogen determined by NMR were used to quantify the CH_x stretching absorption in the infrared spectra of the same films. The infrared spectra reveal that the hydrogen is bonded covalently to the diamond lattice primarily as CH, CH_2 , and CH_3 groups,^{5,6} with some $-\text{OCH}_3$ and $-\text{NCH}_3$ moieties also possible.¹⁰

The ^1H spectra in Figure 4 are well represented by two components, a narrow Lorentzian and a broad Gaussian,⁵ as shown

Figure 4 Static ^1H NMR spectra at 270 MHz of a free-standing diamond film (solid lines). Two components are resolved at 300 K (middle), but the sharp Lorentzian is broadened when the temperature is decreased to 100 K (top). A 300 K ‘hole-burning’ experiment (bottom, dashed line) shows uniform attenuation of both components after selective irradiation of the small band, $\Delta\nu_{\text{sat}}$, indicating dipolar communication among the two resolved proton environments

by the solid line representing a least squares fit to the data, indicating at least two different bonding configurations for hydrogen in polycrystalline diamond. Similar two-component proton lineshapes, with different narrow to broad ratios, have been observed from films deposited by a variety of CVD processes.^{9,10} However, in CVD diamond with relatively high hydrogen concentrations, often only the broad feature can be resolved.²¹

A ‘hole-burning’ NMR experiment shows that these two resolved hydrogen environments are in close proximity.⁵ When a 1 kHz-wide region, 20 kHz from the center of the lineshape, was selectively saturated, uniform attenuation of both components is observed after a 2 ms delay (Figure 4). This indicates that rapid dipolar communication occurs between protons in the two environments, requiring internuclear distances of less than 50 nm. Figure 4 also shows that at 100 K the Lorentzian component is broadened, while the Gaussian component is not significantly affected.⁵ Thus, at room temperature, the narrow Lorentzian lineshape results from motional averaging, while the broad Gaussian line indicates rigidly held hydrogen. The CRAMPS ^1H spectra show an unresolved peak centered at ~ 2 ppm.²⁰

The homonuclear broadening resulting from static distributions of hydrogen bonded in a rigid polycrystalline lattice can be calculated by the van Vleck equation [see equation (1)]. For polycrystalline diamond samples, if all the hydrogen in the Gaussian component were randomly distributed as CH, the resulting $\Delta\nu_{\frac{1}{2}}$ range would be more than

two orders of magnitude smaller than typically observed values of ~ 60 kHz. Randomly dispersed CH_2 groups also provide too little homonuclear broadening. These discrepancies indicate locally high hydrogen concentrations, requiring significant segregation of hydrogen in polycrystalline diamond.^{5,6} However, this analysis cannot distinguish between isolated small clusters and larger groupings of spins.

Possible locations for segregation are hydrogen-decorated defects and voids within the crystal, a heavily hydrogenated phase stable at the deposition temperature or at the grain boundaries in polycrystalline diamond.⁵ If hydrogen was uniformly distributed on a surface, a density of $3 \times 10^{15} \text{ H cm}^{-2}$ would be required to give the observed $\Delta\nu_{\frac{1}{2}} = 60 \text{ kHz}$. This compares favorably with areal densities of 3.1×10^{15} , 2.2×10^{15} , and $1.8 \times 10^{15} \text{ H cm}^{-2}$ for fully hydrogen passivated, unreconstructed $\langle 100 \rangle$, $\langle 110 \rangle$, and $\langle 111 \rangle$ diamond surfaces, respectively. In order to account for the NMR-observed bulk hydrogen incorporation of 0.01–0.22 at.%, monolayer hydrogen coverage of films composed of 0.5–150 μm cubes is required, dimensions which compare favorably to observed crystallite sizes in CVD films.⁶ The structure of hydrogenated surfaces present during growth may resemble those preserved at grain boundaries, which would allow these ^1H NMR measurements to act as a potential test of surface chemistry models of diamond growth.

The assumption of a surface distribution of hydrogen in polycrystalline diamond films is also supported by multiple quantum (MQ) NMR studies.⁸ Figure 5 shows the rate at which groups of protons are effectively correlated with increasing dimensionless MQ excitation time, $M_2^{1/2} \tau$, for

Figure 5 The number of effectively correlated protons (N) versus the dimensionless MQ excitation time, $M_2^{1/2} \tau$. The CaH_2 data ($\bullet$) fall on the universal curve for MQ growth of three-dimensional proton distributions. This growth is faster than for two-dimensional systems, represented by the hydrogenated diamond powder data ($\diamond$). The MQ growth of the three different CVD samples ($\square$, CVD-1; $\triangle$, CVD-2; $\circ$, CVD-3) is similar to that of the hydrogenated diamond powder at early excitation times. Nearly 20 protons are correlated in these films which have <0.5 at.% hydrogen, confirming the presence of large-scale hydrogen segregation. (Adapted from Levy and Gleason⁸)

two hot filament diamond films (CVD-1 and CVD-2) and one DC arc jet film (CVD-3). Initially, the data for the films are coincident with a known surface distribution of protons, hydrogenated diamond powder, and slower than that of known bulk hydrogen distributions, such as exist in CaH_2 . Up to 20 spins were correlated in the films despite the very low (<0.1 at.%) bulk concentrations, confirming the large-scale clustering of hydrogen, most likely in a two-dimensional distribution. The morphology of hydrogen incorporated into these films, as determined by MQ NMR, depends only weakly on the manufacturing process, suggesting that similar surface chemistry has occurred in both types of reactors.

4 FLUORINE-19 NMR

The lower substrate temperatures which have been achieved using fluorine-containing CVD reactants²⁶ opens the possibility of depositing diamond onto materials of low thermal stability, such as organic polymers. In addition, fluorination has been proposed to enhance the chemical inertness and lower the coefficient of friction of diamond surfaces.²⁷ Thus, knowledge of surface passivation of diamond by fluorine is desirable.

Solid state ^{19}F NMR has been used to characterize the surfaces of diamond powder after 100% CF_4 and 98% $\text{CF}_4/2\%$ O_2 radiofrequency plasma treatments.²³ The pure CF_4 plasma results in $7.1 \times 10^{14} \text{ F cm}^{-2}$, a coverage equivalent to approximately half of the available surface bond density. With the addition of 2% O_2 , the equivalent coverage is reduced by roughly an order of magnitude, to $7.4 \times 10^{13} \text{ F cm}^{-2}$. MQ NMR reveals that ^{19}F is not distributed uniformly on either surface.

High-speed MAS was used to average the effects of chemical shift anisotropy (Figure 6). On both surfaces, only CF_x ($x = 1-3$) functionalities were observed, with the predominant species being carbon monofluoride. Only 5–10% of the fluorine was bonded as CF_3 . The isotropic chemical shifts were resolved and assigned relative to CFCl_3 as follows: $\text{CF} = 148 \pm 1 \text{ ppm}$; $\text{CF}_2 = 106 \pm 2$ and 123 ppm ; $\text{CF}_3 = 78 \pm 1 \text{ ppm}$. The peak at 123 ppm was only observed in the CF_4/O_2 plasma-treated sample, and is speculated to be the result of atomic fluorine etching of diamond.

5 SPIN-LATTICE RELAXATION

Paramagnetic defects facilitate spin-lattice relaxation in both natural and synthetic diamond.^{12,13} At a fixed degree of enrichment, an increase in the ^{13}C T_1 qualitatively indicates a lower relaxation center density, hence an increase in crystal quality. The T_1 s of commercial natural diamond powder are on the order of tens of seconds, while significantly longer time constants, on the order of a few hours, can be observed for large, gem-quality natural diamonds. An increase in T_1 has also been observed within a series of CVD diamond films as the morphology, observed by scanning electron microscopy, improved.¹⁷ However, detailed quantitative studies of T_1 behavior, analogous to those on single crystal diamond,¹² are often hindered by the higher complexity of defect distributions in the polycrystalline films.

Paramagnetic defects in diamond result from either unsatisfied bonding arrangements, so-called dangling bonds, present

Figure 6 Room-temperature, high-speed (15 kHz) MAS ^{19}F NMR spectra at 376.5 MHz of diamond powder surfaces, fluorinated by two different methods. (Adapted from Scruggs and Gleason²³)

either internally or at the surface of a crystal or from impurity incorporation. Nitrogen is a common impurity that gives rise to a variety of ESR-active centers.²⁸ Often these sites act as color centers, providing a visible manifestation of their presence. Boron incorporation imparts a blue color, and is sometimes intentionally used to produce p-type semiconducting diamond (type IIb).¹² However, most impurities are unintentionally introduced. For example, ferromagnetic impurities originating from the catalyst are common in HPHT synthetic diamond, and metallic impurities from the hot filament used are common in this variety of CVD film.

The ^{13}C spin-lattice relaxation of diamond can be described by²¹

$$M(t) = M_0[1 - \exp[-(t/T_1)^x]] \quad (4)$$

where x is constrained by the limits, $0.5 \leq x \leq 1.0$, and M_0 is the equilibrium magnetization. For the upper bound, $x = 1.0$, equation (4) represents simple exponential relaxation, as predicted from the Bloch equations. In this case, every ^{13}C site has the same relaxation rate. In diamond, this limit occurs if spin diffusion among the ^{13}C nuclei is fast compared with the rate at which an individual ^{13}C nucleus relaxes as a result of a neighboring paramagnetic site. If the situation is reversed, poor communication among the ^{13}C nuclei requires that each relaxes

directly with a neighboring paramagnetic site. Since there is a distribution of ^{13}C to paramagnetic site distances, a dispersion of spin-lattice relaxation rates results. Fortunately, integration over all possible rates, with appropriate assumptions, simplifies to equation (4) with $x = 0.5$.¹³

An excellent consideration of influence of direct ^{13}C relaxation to paramagnetic defects in comparison to spin diffusion rates in diamond is provided by Hoch et al.¹² Unfortunately, both limits as well as mixed behavior are possible. Spin diffusion is slowed when no ^{13}C enrichment is employed and MAS is used. Thus, behavior approaching the $x = 0.5$ limit has been observed for MAS spectra of samples having natural abundance or a 14% ^{13}C enrichment.^{20,21} In contrast, pure exponential behavior ($x = 1.0$) is observed in static spectra of more highly enriched (22%) samples.¹⁶ Analysis of spin diffusion rates as a function of enrichment suggests that paramagnetic centers are distributed uniformly in polycrystalline CVD diamond films, rather than being localized at grain boundaries.¹⁴

Short spin-lattice relaxation time constants have been reported for both ^1H and ^{19}F bonded to diamond. These fast rates suggest paramagnetic centers contribute to spin-lattice relaxation and are further enhanced by rapid spin diffusion among these clustered, high-gyromagnetic ratio nuclei. For ^1H , room temperature T_1 values are in the range of 5 ms to 1 s.^{8,9,21} These values increase after annealing CVD diamond at 500–750 °C suggesting passivation of paramagnetic centers.⁹ The relaxation appears nonexponential, but exact determination of x [see equation (4)], involves a large degree of uncertainty due to the low signal levels available.^{9,21,23} Also, caution must be applied in directly interpreting x , since multicomponent relaxation, motion, and, in the case of ^{19}F , CSA can also lead to nonexponential relaxation. For ^{19}F , nonexponential spin-lattice relaxation with a time constant of ~ 0.5 s has been observed for two samples at room temperature.²³ The ^{19}F T_1 increases as the temperature is lowered to 150 K, but remains fixed upon further decreasing the temperature to 100 K. This behavior is consistent with changes in the static ^{19}F lineshape, indicating motion is occurring at room temperature.

1 INTRODUCTION TO NMR OF HYDROGEN–METAL SYSTEMS

The exposure of hydrogen to metals often produces significant changes in the physical properties of those metals. The absorption of hydrogen into interstitial lattice sites between metal atoms causes metallic materials to expand their volume, changes the crystal structure, and may change the electronic structure or electrical character of the material. Unable to withstand the strain, some metals fracture into powder, sometimes a useful method of producing powder of ductile metals, but at other times a possibly disastrous result as in the case of hydrogen embrittlement of steels. All the materials included in hydrogen–metal systems (HMSs) are occasionally incorrectly referred to as metal hydrides. As we will see below, metal hydrides do make up the majority of materials in HMSs. Metal hydrides can be either covalent, ionic, or metallic¹ in nature. We will confine our attention to metallic hydride materials.

One of the earliest NMR studies of hydrogen in metals was done some 40 years ago by R. E. Norberg,² who applied hydrogen to the palladium metal wires which made up the rf coil of his NMR probe. Linewidth, Knight shift, and relaxation times of the hydrogen in the rf skin depth of the palladium wires were studied by continuous wave and spin echo techniques.

Some of the most basic NMR studies of HMSs have been the investigation of the underlying physical principles governing hydrogen location and motion at the atomic or ‘microscopic’ level. Long-range hopping or diffusion of hydrogen is currently understood in terms of thermally activated, over the barrier hopping between interstitial lattice sites, which will be discussed, in part, below. Pulse magnetic field gradient NMR to measure hydrogen (and other atomic) diffusivities is discussed elsewhere (see *Diffusion in Solids*). Attempts to characterize tunneling of hydrogen at low temperatures between interstitial vacancies in metals at low temperatures by NMR will be discussed briefly here.

Although NMR is a powerful tool for observing hydrogen interactions in HMSs, interpretation of NMR data cannot be

done properly without other knowledge of the materials. Crystal structure and phase diagram results from X-ray, neutron diffraction,³ and detailed magnetic information from susceptibility measurements are often crucial to the interpretation of NMR results of HMS.

Many of the applied NMR studies of hydrogen, deuterium, and tritium in HMSs have been undertaken to determine the location and motions of hydrogen within the metallic materials in efforts to characterize and improve the hydrogen–metal materials for applications such as purification of hydrogen, hydrogen isotope separation, and hydrogen storage for fuel or energy storage (batteries); or closed cycle, metal hydride refrigerators for remote or applications to vehicles in space.⁴

HMSs include elemental metals, MH_x , with small concentrations of hydrogen, e.g. $x < 0.01$, dissolved in the host material with hydrogen located in interstitial vacancies without significant change in the crystal structure of the metal host, M . These materials are referred to as hydrogen (metal) solid solution (α) phases. The solubility of hydrogen in metal solid solutions often diminishes rapidly with decreasing temperature, forming metal hydride precipitates at lower temperatures. High hydrogen concentrations, $x = H/M$, often extend to $x = 3$ or 4 for metal hydrides, e.g. LaH_3 , SnH_4 , and PbH_4 , where the crystal structure of the hydride (β or γ) phase, e.g. face centered cubic (fcc) (or CaF_2 structure) for YH_2 , is usually quite different from the parent metal, e.g. hexagonal close packed (hcp) for Y , and the density of the metal hydride typically is less than the parent metal density. Intermediate hydrogen concentration samples may be mixed hydrogen–metal solid solution α and metal hydride β phases. The observed NMR spectra and nuclear spin–lattice, R_1 , and spin–spin, R_2 , relaxation rates as functions of temperature may give evidence of the mixed phases (see *Phase Transitions and Critical Phenomena in Solids*).

HMSs include hydrogen solid solutions of elemental metals, binary metal alloys, and intermetallic compounds, and also hydrides of metals, alloys, and intermetallic compounds. In addition, metallic halide compounds⁵ and metal sulfides⁶ adsorb hydrogen to significant degrees and should be included in HMSs. Some alloys and intermetallic compounds do not survive the hydriding process, but will disproportionate into hydrides of one or more of the metals and other compounds. In these cases, the hydride of the constituent metal is more stable than the hydride of the parent material.

Most NMR hydrogen–metal studies are made with samples sealed in quartz tubes to prevent loss of hydrogen upon heating the samples and to prevent oxidation or other contamination. Generally, the metallic nature of the materials requires powdered samples (particle size $\leq 100 \mu m$) to permit the B_1 rf magnetic field to penetrate the metallic particle’s ‘rf skin depth’ uniformly. The spaces between powder particles contain hydrogen gas molecules which represent a characteristic hydrogen over pressure of the particles typical for that material, nominal hydrogen concentration, and sample temperature. The hydrogen gas molecules between particles are in constant exchange with the hydrogen atoms or ions within the metallic particles. The hydrogen exchange rate is often quite low for room temperature, but may be many orders of magnitude greater for $T > 700 K$.

The density of the hydrogen inside some hydrogen storage materials, e.g. $LaNi_5H_6$, is greater than the hydrogen density in liquid hydrogen by a factor of two or three. Generally, the

hydrogen density in the metallic powders is many orders of magnitude greater than the density of gas molecules between powder particles. Thus, the observed hydrogen spectrum is typically the spectrum of the hydrogen in the metal only. Recently, anomalously high proton spin–lattice relaxation rates, R_1 , observed for $T > 700$ K within the metal particles⁷ have been understood in terms of exchange between bulk hydrogen atoms in the metallic powder and the much faster relaxing hydrogen gas molecules between the metallic powder particles⁸ (see *Hydrogen Molecules*).

2 HYDROGEN MOTION IN METALS DETECTED BY NMR

The early measurements of Norberg² demonstrated the motion of hydrogen in palladium. HMSs have been studied by NMR beginning with wideline CW methods measuring rigid lattice or low temperature linewidths and lineshapes. The low temperature or rigid lattice hydrogen linewidth originates from the magnetic interactions of the nuclear dipoles in the solid HMSs. Narrowing of the spectral lines with increasing temperatures gave clear evidence of hydrogen motion or hopping into interstitial vacancies within the solid.⁹ This rapid hopping of hydrogen results in a simple averaging of the local magnetic field B_L or the distribution of magnetic fields ‘seen’ by the hopping proton magnetic dipole moment. These motional narrowing studies yielded activation E_a energies of diffusion and moderately precise estimates of hydrogen jump frequencies, $\nu_j(T)$, or alternately, of hydrogen ‘dwell times’ or mean residence time, $\tau_D(T) = 1/\nu_j(T)$, and hydrogen correlation times, $\tau_c(T)$. With increasing T , when the average hydrogen jump frequencies exceeded the rigid lattice linewidth, the observed spectral lines narrowed. The temperature range for line-narrowing measurements was generally less than 100 K; Figure 1 from Schreiber and Cotts¹⁰ shows multiple line-narrowing graphs of LaH_{2+x} against

temperature. Lanthanum hydride shows the unusual ability to absorb hydrogen between compositions LaH_2 and LaH_3 , maintains an fcc structure, and with each additional hydrogen, every hydrogen atom jumps more rapidly. In most HMSs, with increasing temperature, the average hydrogen jump frequency can easily exceed the proton resonance frequency.

The proton linewidths versus temperature¹¹ in zirconium chloride hemihydride ($\text{ZrClH}_{0.5}$) and zirconium chloride monohydride (ZrClH) are shown in Figure 2. This transition metal halide structure consists of two zirconium metal layers sandwiched between two chlorine layers. Hydrogen is known to reside in interstitial tetrahedral sites between the two zirconium metal layers. In addition, the crystal structures for the hemi- and monohydrides are known to be slightly different, due to the presence of the hydrogen in the material.¹²

Indirect evidence of hydrogen (deuterium) hopping was also observed on studying the ^{93}Nb electric quadrupole perturbed, NMR satellite line narrowing in $\text{NbH}_{0.73}$ and $\text{NbD}_{0.82}$ with increasing temperature.¹³ Figure 3 shows the narrowing of the inhomogeneously broadened ^{93}Nb NMR satellite linewidth. This narrowing can be understood in terms of reducing the randomness (inhomogeneity) of the average value at the niobium ion sites due to the increased rapidity of the hopping motion of the hydrogen (deuterium) ions with temperature and their associated electrical charges in the vicinity of the niobium ion sites. The reduced average EFG at the ^{93}Nb site yielded a narrower NMR satellite linewidth. Thus, the stationary niobium NMR showed evidence of the mobile hydrogen (deuteron) ions hopping.

3 DYNAMIC STUDIES OF HYDROGEN MOTION IN A METAL

The magnetic dipole interactions of hydrogen with other hydrogen magnetic moments, with the host metal nuclear

Figure 1 Proton linewidths ($1\text{G} = 10^{-4}\text{ T}$) plotted against T for different x values. (Reproduced by permission of the American Physical Society from Schreiber and Cotts¹⁰)

moments, paramagnetic impurity moments, and with conduction electron magnetic moments generally govern the flow of spin energy within HMSs. Cross relaxation of protons and host metal nuclei having large nuclear electric quadrupole interactions has been observed. Also, as shown below, the hopping deuteron can be relaxed by interactions of its electric quadrupole moment with fluctuating EFGs within the material.

The observed hydrogen spin-lattice relaxation rate $R_1(\omega, T)$ varies greatly with temperature in HMSs, and is often the sum of several independent $R_1(T)$ rates, each due to separate physical relaxation mechanisms active in the material. Fortunately, these several R_1 rates have different resonance frequency and/or temperature dependences. With this fact in mind, we shall see how one can separate these spin-lattice relaxation mechanisms and thereby begin to characterize the materials.

The observed hydrogen spin-lattice relaxation rate (HSLR) R_1 , in general, may be the sum of several of the following rates:¹⁴

$$R_1 = R_{1d} + R_{1e} + R_{1p} + R_{1CR} \quad (1)$$

where R_{1d} is the magnetic dipole-dipole relaxation of the hydrogen due to other hopping hydrogen. Bloembergen, Purcell and Pound¹⁵ (BPP) were first to suggest the form of relaxation

$$R_{1d} = \frac{1}{T_{1d}} = M_2(T)J(\omega_0, T) \quad (2)$$

where M_2 is a mean-square fluctuating field most commonly thought to be related to the magnetic dipole-dipole interaction of the hydrogen with other magnetic moments. However, in the case of the deuteron, this formalism can also be

Figure 3 Wide line absorption derivative spectra of ^{93}Nb for 300 and 386 K. At 386 K hydrogen jumping rates are sufficiently fast to produce a spatial average of the electric field gradient at the Nb metal sites which narrows the spectra. (Reproduced by permission of Elsevier Science, Inc., from Hwang et al.¹³)

expressed in terms of the fluctuations of the EFG about the deuteron electric quadrupole moment.¹⁶ In this case, R_{1d} is then written R_{1q} (q denoting quadrupolar relaxation). ω_0 is the spin precession frequency in angular frequency units. $J(\omega_0)$ is the power spectrum or spectral density function of the fluctuation magnetic fields (or fluctuating EFGs) within the sample. The simplest form of $J(\omega)$ is the Lorentzian

$$J(\omega) = \frac{\tau_c}{1 + \omega^2\tau_c^2} \quad (3)$$

where τ_c is the correlation time and is strongly temperature dependent. Often τ_c varies exponentially with temperature, where $\tau_c = \tau_0 \exp(-E_a/kT)$ and where $1/\tau_0$ is thought to be the attempt frequency of hydrogen jumping or the high temperature 'rattling' frequency of hydrogen within the interstitial site.

Equation (2) is often written with an additional Lorentzian term, including dipolar interaction terms at 2ω , as

$$R_{1d} = M_2(T) \left(\frac{\tau_c}{1 + \omega^2\tau_c^2} + \frac{4\tau_c}{1 + (4\omega^2\tau_c^2)} \right) \quad (4)$$

This simple description includes no details of the hydrogen interactions with metal nuclear moments or structure considerations of the HMS. It also ignores any orientation dependence of the crystal (sample) with the magnetic field $\mathbf{B}_0$ direction. Nonetheless, this BPP description is quite a good characterization of the hydrogen relaxation in many simple HMSs.

In a detailed description of hydrogen relaxation anisotropy in single crystal HMSs, Hoke et al.¹⁷ gave the relaxation rate

of protons in an hcp single crystal of $\text{ScH}_{0.25}$ as

$$R_1 = \left(\frac{\mu_0}{4\pi}\right)^2 \gamma_H^2 \gamma_S^2 \left(\frac{h}{2\pi}\right)^2 S(S+1) \left(\frac{1}{12} J^{(0)}(\omega_H - \omega_S) + \frac{3}{2} J^{(1)}(\omega_H) + \frac{3}{4} J^{(2)}(\omega_H + \omega_S)\right) \quad (5)$$

following Abragam¹⁸ where γ_H and γ_S are the gyromagnetic ratios of the hydrogen and metal, S is the spin (in this case, ^{45}Sc $S = \frac{7}{2}$), and $J^{(q)}(\omega)$ are spectral density functions which depend on the diffusion model chosen and on the orientation of the crystal in the magnetic field. Within the three spectral density functions $J^{(0)}$, $J^{(1)}$, and $J^{(2)}$ the frequencies $\omega_H - \omega_S$, ω_H , and $\omega_H + \omega_S$ are the difference between hydrogen and metal frequencies, the hydrogen frequency, and the sum of hydrogen and metal frequencies, respectively.

Interestingly, the anisotropy in R_1 originates in the anisotropy of $J^{(q)}(\omega)$, written by Sholl¹⁹ as

$$J_{qq'} = \sum_{\alpha, \beta} \frac{Y_{2q}(\Omega_\alpha)}{r_\beta^3} \frac{Y_{2q'}(\Omega_\beta)}{r_\beta^3} P(r_\alpha, r_\beta, \omega) \quad (6)$$

where Y_{2q} are spherical harmonics, r_α is the distance between the proton and metal spin at time zero, and r_β is the distance between the proton and metal spin at time t . $P(r_\alpha, r_\beta)$ is the Fourier transform of the probability function for the diffusion model chosen.¹⁷

The conduction electron moments in the HMS relax the hydrogen moment through a contact hyperfine interaction the same as is associated with the Knight shift.^{18,20} The relaxation rate R_{1e} is proportional to the temperature and the square of the Knight shift (see Section 4 for a simple description of the Knight shift) and the square of the density of unpaired electronic (moment) states at the Fermi energy $N(E_F)$. Generally, the better the conductivity of the metallic material the greater the electronic relaxation rate R_{1e} :

$$R_{1e} = \frac{1}{T_{1e}} \propto N^2(E_F)T \quad (7)$$

For a simple metallic material, combining the Knight shift with relaxation rate,

$$T_{1e} T K^2 = \frac{T}{R_{1e}} K^2 = \frac{h/2\pi \gamma_e^2}{4\pi k \gamma_n^2} \quad (8)$$

where γ_e and γ_n are the electron and nuclear (hydrogen) gyromagnetic ratios. This equation is known as the Korringa or Heitler-Teller-Korringa (HTK) relation,²¹ where the Knight shift and R_{1e}/T are theoretically constant in temperature and R_{1e}/T or $1/T_{1e}T$ is often used to characterize the electronic relaxation in HMSs.

Unwanted paramagnetic ion concentrations, ignored in several NMR studies of HMSs, have shown unusual, anomalous relaxation rates and 'extra features' in the measured HSLR which have been attributed to a fictitious complex or additional diffusion mechanism. Phua et al.²² showed that many such unusual or extra relaxation mechanisms were most likely due to the existence of residual paramagnetic impurities (dirt) in the host metals present at the time of the formation of the HMS. That study showed, generally, that the extra spin-lattice

Figure 4 Proton spin-lattice relaxation time T_1 vs. $1000/T$ in YH_2 vs. Gd impurity concentration. (Reproduced by permission of American Physical Society from Phua et al.²²)

relaxation rates, R_{1p} , were linearly proportional to the concentration of paramagnetic impurities present. In addition, extra minima in $\log(T_1)$ versus $1/T$ were a direct result of the impurity relaxation; see Figure 4 for evidence of the suppression of $\log(T_1)$ versus $1/T$ and 'extra minima'. The paramagnetic moments produce a relaxation rate R_{1p} in HMS and can relax hydrogen by spin diffusion at low temperature in the low hydrogen diffusion regime. At higher temperatures, in the fast diffusion regime, hydrogens approach the stationary paramagnetic ions by rapid hopping within the sample and are relaxed via direct dipolar interactions with the paramagnetic impurity ions.

The cross relaxation of the proton, R_{1cr} , with certain host metal nuclei which have large electric quadrupole moments and subsequently large quadrupole interactions was recognized for protons in HMS at low temperatures (see Figure 5) where hydrogen hopping rates are slow. The strong nuclear electric quadrupole interactions of the metal nuclei, e.g. ^{175}Lu in $\text{LuH}_{0.20}$ ²³ and ^{181}Ta in Ta_2H ²⁴ are many tens of megahertz in extent (width) and are only perturbed by the static magnetic field B_0 required for proton resonance. Although the ^{93}Nb quadrupole moment and interaction in $\text{V}_x\text{Nb}_{1-x}\text{H}_y$, for example, is weaker than ^{181}Ta in Ta_2H and ^{175}Lu in $\text{LuH}_{0.20}$, for frequencies $f_{\max} < 24$ MHz, protons also cross relax to ^{93}Nb . When the proton resonance frequency matches one of the many spectral features of the metal NQR, spin polarization energy is transferred from the proton to the metal nucleus. The spin polarization energy is taken from the metal nucleus by the conduction electron interaction to the lattice because the contact hyperfine interaction is much stronger and thus faster (or higher rate) for the metal nucleus than for the proton. Figure 6 shows the proton cross relaxation to ^{181}Ta in $\text{TaH}_{0.32}$ as a function of proton resonance frequencies²⁴ (for a series of magnetic field values) while at $T = 130$ K. The calculation of the cross relaxation as a function of proton frequencies is described by Lichty et al.²⁴

Figure 5 Proton spin-lattice relaxation rates R_1 vs. $1000/T$ in LuH_x at 12, 40 and 65 MHz. Cross relaxation between the protons and the ^{175}Lu nuclear electric quadrupole broadened NMR lines can be seen at low temperatures in the loss of temperature dependence for $T \leq 400$ K. (Reproduced by permission of R. Oldenbourg Verlag from Torgeson et al.²³)

Figure 7 shows the total spin-lattice relaxation rate versus reciprocal temperature in schematic form, typical of many HMSs with the several component relaxation rates identified.

4 DEUTERON LINESHAPE FOR COMBINED ELECTRIC QUADRUPOLE AND KNIGHT SHIFTS

The Knight shift of hydrogen results from a small magnetic field at the hydrogen nucleus in an HMS from the conduction electron wave function $|\psi(0)|^2 \neq 0$ for the s electron character of the conduction electrons. This is often called the ‘contact hyperfine interaction’ or Fermi contact term. The application of the B_0 field causes a small paramagnetic polarization of the conduction electrons, called the Pauli paramagnetism, where $M_s = \chi_s B_0$ and χ_s is the Pauli spin susceptibility. χ_s can be related to the density $N(E_F)$ of unpaired conduction electron states at the top of the conduction electron distribution or at the Fermi energy via the Pauli susceptibility $\chi_s = \frac{1}{2}(\gamma_e h)^2 N(E_F)$. The Knight shift can be written simply as $K \approx \chi_s |\psi(0)|^2 / N$. The Knight shift causes a fractional change in the proton (deuteron) gyromagnetic ratio, that is, a small shift in position of the hydrogen resonance ΔH for fixed frequency or $\Delta \nu$ for

Figure 6 Proton cross-relaxation data (●) to ^{181}Ta nuclear electric quadrupole broadened NMR lines in $\text{TaH}_{0.32}$ as a function of a series of proton resonance frequencies at 130 K. See Lichty et al.²⁴ for details of the theoretical calculations and the three curves presented. The analysis yielded a ^{181}Ta nuclear electric quadrupole frequency $\nu_Q = 43$ MHz and electric field gradient asymmetry parameter $\eta = 0.35$. (Reproduced by permission of American Physical Society)

fixed field measurements

$$K = \frac{\Delta H}{H} = \frac{H_R - H_M}{H_R} = \frac{\Delta \nu}{\nu} = \frac{\nu_M - \nu_R}{\nu_R} \quad (9)$$

where subscript M refers to the metal field or frequency and R refers to the reference (solution or free ion) field or frequency. These fractional shifts are generally independent of the field or frequency.

Knight shifts of hydrogen in HMSs are generally quite small in magnitude compared with Knight shift values of metals, and often smaller in field shift magnitude ΔH than the dipolar broadened width or the B_L local magnetic field in the solid. However, the magnetic moment of the deuteron is smaller than the proton by a factor of 3.3, and effects of local magnetic fields are correspondingly smaller than for the proton. Figure 8 shows the combined effects of ^2D nuclear electric quadrupole interaction and Knight shifts²⁵ in a sample of $\text{NbD}_{0.76}$. The general subject of combined nuclear electric quadrupole interactions and Knight shift interactions in metals was first presented by Jones et al.²⁶ Since the ^2D spin $I = 1$, there are $2I + 1$ or 3 levels and two transitions and no ‘central line’. These two transitions for spin $I = 1$ are commonly referred to as the Pake doublet,²⁷ following the terminology established by George Pake in 1948 for the interaction of two coupled protons of combined spin $I = 1$ in the water of hydration in gypsum.

$\text{NbD}_{0.76}$ is orthorhombic in structure and thus the EFG and the Knight shifts must be described by tensors. The principal

Figure 7 Generalized proton spin–lattice relaxation rate R_1 contributions vs $1000/T$. These relaxation rates are: conduction electron, R_{1e} ; long range diffusion/dipole–dipole, R_{1d} ; paramagnetic impurity ion, R_{1p} ; and cross-relaxation to quadrupole (metal) nucleus, R_{1cr} . The relative weighting of these mechanisms depends on the purity and physical details of the HMS sample studied

axis system of the EFG has three separate components V_{xx} , V_{yy} , and V_{zz} , the second derivatives of the crystalline potential with respect to the coordinates x , y , and z . Note that $\nabla^2 V = V_{xx} + V_{yy} + V_{zz} = 0$ is Laplace's (electrical) equation. In the principal axis system, $|V_{xx}| < |V_{yy}| < |V_{zz}|$. The EFG asymmetry parameter for $\text{NbD}_{0.76}$ is $\eta = (V_{xx} - V_{yy})/V_{zz} = 0.11$. If η were equal to 0, then $V_{xx} = V_{yy}$ would require axial symmetry, i.e. at least three-fold rotational symmetry about the z axis. $\eta \neq 0$ implies the $\Delta m = \pm 1$ transitions $-1 \leftrightarrow 0$ and $0 \leftrightarrow +1$ in combination with the K_x , K_y , and K_z Knight shift components will produce different frequency dependences for the two transitions or ^2D 'powder' lineshapes.²⁵ The width of the pattern essentially measures the strength of the deuteron electric quadrupole interaction described by the lowest pure quadrupole frequency $\nu_Q = 3eQV_{zz}/2h = 49.3 \text{ kHz}$, where eQ is the deuteron quadrupole moment, V_{zz} is the principal component of the EFG tensor and h is Planck's constant. Incidentally, $\nu_Q = 3eQV_{zz}/[2I(2I-1)h]$ is the best measure of the strength of the quadrupole interaction relative to the strength of the NMR interaction characterized by ν_0 , the Larmor frequency.²⁸

For powdered metal hydrides with less than cubic crystal symmetry, the single grain particles' major symmetry axes will simply point in random directions in space. However, with an applied magnetic field switched on, the majority of particles' major symmetry axes will be nearly perpendicular to the field direction and a small minority of crystal symmetry directions will point along the field direction. This produces the well

Figure 8 (a) Deuteron absorption curve vs. frequency for $\text{NbD}_{0.56}$, (b) derivative of observed deuteron absorption curve, and (c) calculated deuteron absorption derivative curve lineshape. (Reproduced by permission of Academic Press from Torgeson et al.²⁵)

known $\sin \theta$ dependence of the distribution of powder particle orientations with respect to the magnetic field direction. As pointed out by Jones et al.²⁶ the major peaks of the absorption spectrum are due to 'singularities' at the perpendicular ($\theta = 90^\circ$) powder grains, and the smaller 'steps' at the extremes of the spectrum are due to those particle crystallites nearly parallel ($\theta = 0^\circ$) to the magnetic field.

The deuteron Knight shift, as for all hydrogen Knight shifts, originates from the contact hyperfine interaction of the conduction electrons at the deuteron (hydrogen) nucleus. In the HMS, the conduction electrons are attracted or 'cored' to the hydrogens in the same way conduction electrons are attracted to the metal nuclei. This, of course, makes the conduction electron wave functions more complex than in the pure metal, alloy, or intermetallic compound. The presence of

the hydrogen may actually change the electronic character of the HMS by changing the conduction electron wave functions and by the hydrogen donating an electron to the conduction band when hydrogen is absorbed, which may greatly modify the electronic band structure of the HMS.

The effect of the Knight shifts on the observed lineshape is simply a small displacement of the resonance position due to an additional magnetic field at the nucleus from the contact hyperfine interaction. For a non-cubic metal or HMS, the magnitude of the shift of the resonance is dependent upon orientation of the crystalline axes of the grain with respect to the field direction. Figure 8 (a) shows the observed absorption curve, (b) a derivative of the observed absorption and (c) a calculated absorption derivative with appropriate Knight shift and EFG components included. Absorption derivative lineshapes actually show more subtle lineshape features than do the absorption curves. Absorption derivatives lineshapes were commonly recorded in field or frequency scanned CW wideline studies in past years because of the use of lock-in amplifiers and small amplitude magnetic field or frequency modulation to record spectra.

5 LOW TEMPERATURE LOCAL HYDROGEN MOTION AND HYDROGEN TUNNELING IN HMSs

Scandium, yttrium, and lutetium plus other rare earth hcp metals provide a nearly unique opportunity to observe hydrogen dissolved in metals and measure hydrogen motions in metals at temperatures below 150 K. Unlike many transition metals, scandium, yttrium, and lutetium can maintain up to 30 at% hydrogen in solution without precipitating any of the hydride phase²⁹ down to 4 K or without transforming to another crystal structure.

Lichty et al.³⁰ measured proton R_1 s in $\text{ScH}_{0.27}$ ($\text{H}_{0.18}$) and found both an electronic relaxation R_{1e} and a weak low temperature motional relaxation peak R_{1L} near 60 K (105 K). That peak moved with the proton resonance frequency in a manner similar to the movement of R_{1d} , the over the barrier hopping, long range diffusion relaxation rate peak at much higher temperatures. In Figure 9 we see these low temperature data for two proton frequencies. The R_{1L} motional relaxation peak is superimposed on the R_{1e} electronic relaxation, which is linear in temperature T ($R_{1L} = R_1 - R_{1e}$; R_{1L} will be discussed below).

The location of hydrogen (deuterons) in the scandium hcp lattice was studied by neutron scattering.²⁹ Deuterons were found to prefer to form pairs with a scandium atom between. From these neutron scattering studies, models of hydrogen ordering in chains of paired hydrogens in scandium were proposed.

The pairing of hydrogen with a scandium metal between is an interesting and unusual ordering. However, not all hydrogens are paired with a metal between. Some of the hydrogens are unpaired and thus occupy vacant tetrahedral (T) sites in a random or inhomogeneous manner. The random occupation of hydrogen in metal–solid solutions has been referred to by Barnes¹⁴ as a proton glass. The result of an inhomogeneous hydrogen occupation can be seen in the proton spin–lattice relaxation rate data and will be explained below.

The scandium hcp lattice has two adjacent, closely spaced interstitial T sites along the c axis where hydrogen is known²⁹

Figure 9 Proton spin–lattice relaxation rate (R_1) in $\text{ScH}_{0.27}$ as a function of temperature at 24 and 62 MHz. Proton R_1 in $\text{YH}_{0.18}$ at 24 MHz ($\bullet$) shows a weak peak at ~ 105 K. The peak heights are due to the relaxation of the proton's tunneling motion and proton dipole 'collisions' with fixed (^{45}Sc or ^{89}Y) metal nuclear magnetic moments. Note the ^{89}Y moment is $< 1/20$ of the ^{45}Sc moment. (Reproduced by permission of the American Physical Society from Lichty et al.³⁰)

to sit in one of the sites. These two sites are too closely spaced to permit two hydrogens to occupy both sites simultaneously.³¹ The local motion is understood to be one hydrogen moving between these two closely spaced T sites. Activation energies derived from a 'local over a small barrier' hopping model were found to be $E_a \approx 50$ meV, much smaller than the nominal 500 meV activation energies typical of long-range hopping over a barrier found for activation energies in higher temperature hydrogen diffusion. Lichty et al.³⁰ were able to fit the proton spin–lattice relaxation rates versus $1000/T$ with two separate and quite different models for hydrogen hopping over an energy barrier. As can be seen from Figure 10, the data are not symmetrical about the peaks of the three relaxation curves. The slope of the three curves on the high temperature (low $1/T$ values) side of the peak is much greater than the low temperature (higher $1/T$ values) slopes. Symmetrical $\log R_1$ versus $1/T$ curves in HMSs is a signature of hydrogen hopping where there is one unique activation energy typifying a simple hopping process and/or a simple and often cubic solid. Symmetrical $\log R_1$ or $\log T_1$ vs $1/T$ curves are often referred to as BPP type behavior. The relaxation rate curves in Figure 10 show the signature of hydrogen motion in a disordered solid with a distribution of activation energies. This subject will be discussed at length below. Lichty et al.³⁰ were able to fit the data with two hopping models, one assuming a distribution of activation energies and a second model with a correlation

Figure 10 Proton spin–lattice relaxation rate in $\text{ScH}_{0.27}$ vs. $1000/T$ for proton resonance frequencies 12, 40, and 90 MHz fitted with a thermally activated over the barrier hopping model and a distribution of activation energies. (Reproduced by permission of the American Physical Society from Lichty et al.³⁰)

function having a stretched exponential character. Localized hydrogen motion has also been found by Skripov et al.³² in TaV_2H_x in the temperature range 10–100 K.

Tunneling of hydrogen from one tetrahedral interstitial site to an adjacent empty T site at low temperature is an alternate mechanism rather than hydrogen thermally activated hopping over a low energy barrier. Svare et al.³³ suggested that the same proton spin–lattice relaxation data of Lichty et al.³⁰ in $\text{ScH}_{0.27}$ could also be described by hydrogen tunneling between adjacent T sites in the Sc hexagonal close packed lattice. The potential wells for the two sites were thought to have sinusoidal curvature near the bottoms. The two wells of the adjacent T sites were also thought to have different minimum energies, that is, the wells were asymmetric. In fact, Svare et al.³³ suggested the asymmetry, A , for the hydrogen–scandium metal solid solution would have a distribution of minimum energy difference values typical of an inhomogeneous hydrogen solid solution or proton glass. With increasing temperature, the tunneling model must include a tunneling mechanism not appropriate (or yet thermally switched on) at lower temperature. Figure 11 shows the proton spin–lattice relaxation data of Lichty et al.³⁰ fit with this tunneling model. The data fit adequately this tunneling theory and support the proposition that hydrogen tunneling exists in scandium at low temperatures. Hydrogen tunneling in scandium was also found by Leisire et al.³⁴ in a resonant ultrasound spectroscopy (not an NMR technique) study of $\text{ScH}_{0.25}$ and $\text{ScD}_{0.18}$ employing small scandium single crystals.

6 SPIN–LATTICE RELAXATION IN AMORPHOUS HYDROGEN–METAL SYSTEMS

An amorphous metal alloy may be formed by extremely rapid cooling of the molten metal alloy. Such materials are often referred to as metallic glasses. An amorphous alloy is a

Figure 11 Low temperature proton spin-lattice relaxation rates $R_{\text{IL}} \equiv T_{\text{IL}}^{-1}$ versus reciprocal temperature in two hcp scandium–hydrogen solid solution compositions. (a) $\text{ScH}_{0.27}$ and (b) $\text{ScH}_{0.11}$ at 24 MHz (+), 40 MHz (x), and 90 MHz (•), respectively. The curves represent the fits of the tunneling model with a distribution of asymmetric energy well minima for hydrogen tunneling between adjacent tetrahedrally coordinated interstitial (T) sites. Data are from Lichty et al.³⁰ and tunneling model can be found in Svare et al.³³

disordered metal and is without long range topological order. There may be short range or compositional order in amorphous alloys. These amorphous materials are then hydrided by more or less conventional means, but care must be taken not to heat the material high enough to ‘recrystallize’ the amorphous sample. This may be somewhat difficult as the absorption of hydrogen by metals is generally an exothermic reaction.

Bowman³⁵ points out that metallic alloy glasses must contain one of certain metals, i.e. titanium, zirconium, hafnium, palladium, or a rare earth metal, for the glass to be able to hold hydrogen, $\text{H}/\text{M} > 0.1$, where M is the total metal content. Even with one of these metals in the alloy, an alloy glass may not be formed upon quenching.

Hydrides of metallic glasses generally have quite different hydrogen motions, with lower hydrogen diffusion activation energies and spin–lattice relaxation rates than do hydrides of the crystalline HMSs of similar composition as we shall see below. In the case of crystalline and amorphous Zr_2PdH_x , Bowman et al.³⁶ point out the $\log T_1$ versus $1000/T$ plots for $\text{Zr}_2\text{PdH}_{2.90}$ and amorphous $\text{a-Zr}_2\text{PdH}_{2.90}$ are noticeably

Figure 12 Proton spin-lattice relaxation times vs. $1000/T$ for crystalline $\text{Zr}_2\text{PdH}_{1.84}$ and $\text{Zr}_2\text{PdH}_{2.90}$ at 40 MHz and amorphous $\text{Zr}_2\text{PdH}_{2.90}$ at 34.5 MHz, and proton relaxation times for crystalline and amorphous $\text{Zr}_2\text{PdH}_{2.90}$ vs. $1000/T$. The latter curve shows hydrogen diffusion at lower temperatures and with lower activation energy (slope of T_1 vs. $1000/T$ curve) than the crystalline $\text{Zr}_2\text{PdH}_{2.90}$. (Reproduced by permission of R. Oldenbourg Verlag from Bowman et al.³⁶)

different. The crystalline and amorphous curves have minima at different temperatures and have different slopes or diffusion activation energies. Generally, the amorphous samples display more rapid hydrogen diffusion at lower temperatures and have lower activation energies for diffusion than do the crystalline equivalents. This can be seen in Figure 12. A simplistic explanation of this effect may relate in part to the fact that the glassy HMSs have a somewhat lower density and have more 'open' paths for hydrogen to hop through than the crystalline equivalents. A more complete description of hydrogen motion must also include the differences in electronic character known to exist between the glassy and crystalline HMSs.

1 INTRODUCTION

Silica (SiO_2) is one of the most abundant materials on Earth.¹ If the wide range of silicate minerals in which silica 'formally' occurs is included, one can account for more than 60% of the Earth's crust in terms of silica. From the industrial point of view, the number of applications of silica is enormous, and we make no attempt to represent them all here. These technological applications of silica include its use in separations (e.g. column chromatography), in composite materials, in consumer products (e.g. as thickening agents), in immobilized reagents (e.g. heterogeneous catalysts), and even in foods. Although a variety of high-surface-area forms of silica are important, including precipitated and fumed silicas, in this article we will focus mainly on samples originating as *silica gels*, i.e. silica samples precipitated from the products of reactions such as:

The materials prepared in this manner tend to have high surface areas and high porosities, although these properties depend substantially on details of the preparation conditions. Most of the technologically important properties of silica depend substantially on the characteristics of the silica *surface*, e.g. the numbers, types, distributions, and reactivities of silanols, i.e. Si-OH groups, at the silica surface.

A priori, it would appear that the spin- $\frac{1}{2}$ nuclides ^{29}Si (4.7% natural abundance) and ^1H ($\sim 100\%$ natural abundance) should be useful for characterizing the silica surface, and possibly also the quadrupolar nuclides ^{17}O ($I = \frac{5}{2}$, 0.04% natural abundance) and ^2H ($I = 1$, 0.02% natural abundance). Clearly, for these quadrupolar nuclides to be useful, isotopic enrichment is required, but that has not been a major difficulty. Indeed, there has been a great deal of NMR work done on silicas and silica-based systems,²⁻⁵ and it would be impossible to review it all comprehensively here, because of reasonable space limitations. Furthermore, because of restrictions on space, it will not be possible to list all of the worthwhile studies in this research area. For these reasons, the convenient approach of emphasizing studies from our own laboratory is adopted, with apologies to those who feel their work may have been neglected.

2 NMR STRATEGIES FOR SILICA SURFACE SELECTIVITY

2.1 The Need

With any NMR experiment on a solid, a technique that provides no major detection advantage to nuclei at the surface will generate spectra that are dominated by peaks due to nuclei that are in positions in the interior (bulk) of a particle, because the number of nuclei that constitute the bulk of a particle will typically be much larger than the number of corresponding nuclei in analogous structural sites at the surface (unless the surface area is very large, say, $\gg 100\text{ m}^2\text{ g}^{-1}$). This intensity dominance by peaks due to bulk sites can be overcome if (1) the nuclei being observed are located only (or largely) at the surface or (2) the method of generating the polarization to be observed discriminates strongly in favor of nuclei at the surface. The former situation often obtains for protons in a typical silica, because most of the protons in such systems exist at the surface as covalently attached $-\text{OH}$ groups (vide infra), as physisorbed H_2O , or as covalently attached structures that result from derivatization processes.

Perhaps the most obvious strategy for preferentially or selectively polarizing surface nuclei in the presence of an overwhelmingly larger number of nuclei in analogous structural sites in the interior would be to use a relaxation reagent that can, at least briefly, interact with the surface and thereby relax the surface nuclei. Although surprisingly little effort seems to have been expended in this direction, one must note the elegant ultra-low-temperature ($\sim 10\text{ mK}$) NMR studies of Waugh and co-workers,⁶ who have used the relaxation effects of ^3He impinging on a surface for the selective relaxation of nuclei at the surface. Other surface-selective (or preferential) relaxation mechanisms would seem possible via the dipolar mechanism of impinging species with large nuclear magnetic moments (say, ^1H or ^{19}F) or even the electron spin magnetic moments of paramagnetic relaxation agents. In the case of paramagnetic surface relaxants, the possibility of dynamic nuclear polarization (DNP)⁷ of surface nuclei from adsorbed paramagnetic species seems attractive, possibly with the Overhauser mechanism operating if the adsorption is rapidly reversible, or the solid state mechanism if the adsorption/desorption process is very slow. Possibilities would also appear to exist for surface-selective relaxation mechanisms based on quadrupolar relaxation of a nuclide with $I > \frac{1}{2}$ (e.g. ^2H or ^{17}O) due to rapid, reversible adsorption/desorption causing a modulation of the local electric field gradient. Recent progress in the surface transfer of ^{129}Xe polarization that has been dramatically enhanced via electron $\rightarrow$ nuclear polarization transfer (e.g. from optically pumped rubidium) is promising for not only providing a surface-selective NMR strategy, but also for providing huge enhancements in the effective sensitivity of NMR detection at surfaces.⁸

2.2 Cross Polarization

To date, the most popular and generally successful surface-selective polarization strategies have been based on $^1\text{H} \rightarrow \text{X}$ cross polarization (CP),⁹ where X is a nucleus present at the surface (and presumably also with the bulk).^{10,11} These strategies are often based on the assumption that essentially all

Figure 1 Cross polarization as a surface-selective strategy, showing only protons near the (hatched) surface region, as covalently attached hydroxyls, physisorbed water, or physisorbed acids (B–H) of some other type. (Taken from Maciel and Ellis⁴)

(or, at least, most) of the protons in the system are present at the surface and on the fact that cross polarization depends upon a static component of the ^1H –X dipolar interaction, which has an inverse cube dependence on the ^1H –X internuclear distance (in many cases the cross polarization rate appears to have an essentially r^{-6} dependence). Cross polarization was developed during the early 1970s by Pines, Gibby, and Waugh.⁹ Its early impact was primarily the dramatic increase in ^{13}C signal-to-noise ratio in NMR experiments on organic solids, which rendered such experiments especially attractive when carried out with magic angle spinning (MAS), as demonstrated first by Schaefer and Stejskal.¹² From the point of view of surface applications, at least as important as the effective increase in sensitivity is the above-mentioned dependence of the cross-polarization rate on internuclear distances. Figure 1 displays the essence of a surface-selective CP strategy, in which only those X nuclei that are close enough to the surface (within, say, 5–6 Å, as represented by the ‘cross-hatched’ area) can be cross polarized by surface protons. The more remote X nuclei in the ‘interior’ or ‘bulk’ of the material are not cross polarized efficiently. Hence, the efficiency, or dynamics, of cross polarization can be used to discriminate in favor of the surface nuclei.

3 $^1\text{H} \rightarrow ^{29}\text{Si}$ CP IN SILICAS

3.1 Silica Gels and Derivatized Silica Gels

In 1980, Sindorf and Maciel^{10,11} published the first high-resolution example of the use of $^1\text{H} \rightarrow \text{X}$ cross polarization for surface-selective X detection in a demonstration of $^1\text{H} \rightarrow ^{29}\text{Si}$ CP in silica gel. Since that time $^1\text{H} \rightarrow ^{29}\text{Si}$ CP has remained the most popular application of this strategy, although there has been significant success with applications to other types of systems. Figure 2 shows typical ^{29}Si spectra of silica gel and related samples obtained by CP MAS (cross polarization and magic angle spinning) and DP MAS (direct polarization, based on ^{29}Si spin–lattice relaxation, not CP). The DP MAS spectrum [Figure 2(a)] of an undried silica gel is dominated by the peak due to $(\text{SiO})_4\text{Si}(\text{Q}_4)$ sites, which represent the bulk (nonsurface regions) of silica particles. The ^{29}Si CP MAS spectrum of an undried silica gel [Figure 2(b)] selects primarily surface sites and shows the following three peaks: a peak at –89 ppm (relative to liquid TMS) due to

Figure 2 ^{29}Si MAS spectra of silica gel samples. (a) DP MAS spectrum of an undried sample. (b) CP MAS spectrum of the same sample as in (a). (c) CP MAS spectrum of a sample dehydrated under vacuum at 209 °C. (d) Sample derivatized with $(\text{CH}_3)_3\text{SiCl}$. (Taken from Maciel⁵)

$(\text{SiO})_2\text{Si}(\text{OH})_2$ (geminal, Q_2) sites; a peak at –99 ppm arising from $(\text{SiO})_3\text{SiOH}$ (single silanol, Q_3) sites; and a peak at –109 ppm from the Q_4 (siloxane) sites near the surface. These peak assignments can be made on the basis of the usual kinds of empirical chemical shift correlations with structure from liquid sample data on silicic acid solutions. However, the dynamics of the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP process can also be used to make these assignments.

Figure 3 shows the results of a variable contact time CP experiment, in which the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP contact period (t_{cp}) is varied in order to elucidate the $^1\text{H} \rightarrow ^{29}\text{Si}$ CP (relaxation) time constant (T_{Hsi}) for each ^{29}Si peak. The early (small t_{cp}) part of such curves is typically dominated by the rate of CP transfer, as characterized by the rate constant T_{Hsi}^{-1} , and the latter part of such curves is usually determined by the rate constant of the rotating frame spin–lattice relaxation of the protons responsible for polarization transfer to the observed silicons, as characterized by the time constant, $T_{1\rho}^{\text{H}}$ (assuming $T_{1\rho}^{\text{H}}/T_{\text{Hsi}}$). These curves can be analyzed mathematically in terms of equation (1),¹³

$$M(t_{\text{cp}})/M^* = \frac{1}{1 - T_{\text{Hsi}}/T_{1\rho}^{\text{H}}} (e^{-t_{\text{cp}}/T_{1\rho}^{\text{H}}} - e^{-t_{\text{cp}}/T_{\text{Hsi}}}) \quad (2)$$

Figure 3 Variable contact time ^{29}Si CP MAS plots for silica. (Taken from Maciel and Sindorf¹⁰)

where $M(t_{\text{cp}})$ is the ^{29}Si magnetization generated by ^1H – ^{29}Si CP as a result of a CP contact period t_{cp} , and M^* is the ‘ideal’ maximum ^{29}Si magnetization that would be generated if $T_{1\rho}^{\text{H}}$ and T_{HSi}^{-1} were both infinite. This analysis shows that T_{HSi}^{-1} for the -89 ppm peak is roughly twice that of the -99 ppm peak, which in turn is an order of magnitude larger than the T_{HSi}^{-1} value for the -109 ppm peak. In terms of the number and distances of nearby protons, the ^{29}Si chemical shift assignments given above in terms of Q_2 , Q_3 , and Q_4 sites are entirely consistent with these T_{HSi} determinations.

3.2 Dehydration of Silica

The ^{29}Si CP MAS spectra collected in Figure 2 also represent two important classes of chemical transformations of silica surfaces that were studied by ^{29}Si CP MAS spectra by Sindorf and Maciel.^{10,11,14–18} Figure 2(c) shows a spectrum obtained on a silica gel sample that has been dehydrated under vacuum at 209°C . One can see in this spectrum the subtle redistribution of peak intensity and the dramatic line broadening relative to the spectrum observed on an ‘air hydrated’ silica gel sample. These changes, especially the line broadening, are presumably due to a redistribution of hydrogen bonding patterns, and perhaps bond angles and bond lengths (and strains) introduced with the removal of the (predominantly physically) adsorbed water of the ‘hydrated’ and essentially ‘annealed’ silica surface represented in Figure 2(b). Such experiments carried out over a wide range of dehydration temperatures, and corresponding rehydration experiments, have revealed valuable information on the effects of dehydration and rehydration on the silica gel surface.

3.3 Silylation of Silica

The ^{29}Si CP MAS spectrum shown in Figure 2(d) represents a sample prepared by the silylation of a silica gel by $(\text{CH}_3)_3\text{SiCl}$. This silylation reaction is a member of an important class of derivatizations of the silica surface, represented by the following chemical equation:

where X represents a labile leaving group (e.g. Cl or OCH_2CH_3) and Si represents a silanol site on the reactant silica surface or a corresponding derivatized silica site in the reacted sample. Such reactions are important, or potentially important, technologically—for the preparation of stationary phases for chromatographic separations, as a means of immobilizing reactive chemical centers (e.g. catalytic sites), in coupling agents for composite materials, and for a wide range of other applications in which it is desired to anchor or ‘immobilize’ a chemically important moiety. Peak d in the spectrum of Figure 2(d), at ca. 10 ppm, is assigned to the trimethylsilyl group covalently attached to the silica surface. Clearly the silylation process has brought about a change of intensities of peaks a, b, and c in Figure 2(b), corresponding to the $(\text{SiO})_2\text{Si}(\text{OH})_2$ or Q_2 sites, the $(\text{SiO})_3\text{SiOH}$ or Q_3 sites, and $(\text{SiO})_4\text{Si}$ or Q_4 sites, at the underivatized surface. At the relatively low level of structural detail represented by the Q_2 , Q_3 , Q_4 notation, the silylation process transforms Q_2 sites into Q_3 sites, and Q_3 sites into Q_4 sites, and these changes are seen by comparing the spectra in Figure 2(b) and (d). By examining such intensity changes systematically, it has been possible to elucidate important reactivity patterns in these systems.^{10,11,14–18} Indeed, ^{29}Si CP MAS NMR, along with supporting data from ^{13}C CP MAS experiments, can serve as an analytical technique for monitoring chemical reactivity

Figure 4 ^{29}Si (right) and ^{13}C (left) CP MAS spectra of silica gel derivatized with $(\text{CH}_3)_2\text{Si}(\text{OCH}_2\text{CH}_3)_2$. (a) Product of reaction with predried silica at 138°C . (b) Product of reaction with predried silica at 240°C . (c) Product of reaction with undried silica at 115°C . (d) Sample (c) heated in air at 150°C . (Taken from Sindorf and Maciel¹⁷)

Figure 5 ^{29}Si CP MAS spectra of APTS-modified silica gels. Each column of spectra corresponds to the drying temperature of silica gel (°C; RT = room temperature) under vacuum prior to reaction in dry toluene, or aqueous reaction conditions (AQ). Postreaction treatment (curing) temperature shown on the left. Structural assignments given at the bottom. (Taken from Caravajal et al.¹⁹)

patterns, e.g. the relative reactivities of the various types of silanols on a silica surface.

The complex chemistry that can occur on a silica surface after silylation by a reagent with more than one leaving group (X), e.g. $\text{RR}'\text{SiX}_2$ or RSiX_3 , is also amenable to study by CP MAS NMR.¹⁷ In the ^{29}Si CP MAS spectra shown in Figure 4 one sees that the product formed initially from the reaction of silica with $(\text{CH}_3)_2\text{Si}(\text{OCH}_2\text{CH}_3)_2$ depends on the reaction conditions and predrying of the silica, and can be converted by the moisture in air [Figure 4(c), (d)] to products in which $\text{Si-OCH}_2\text{CH}_3$ moieties are replaced by Si-OH and ultimately Si-OSi- moieties. In this case, ^{13}C CP MAS spectra are also useful, because they detect the presence and amount of residual $\text{Si-OCH}_2\text{CH}_3$ moieties.

The ^{29}Si CP MAS spectra shown in Figure 5 represent an even more complex derivatized silica system, a series of samples prepared by the silylation of silica with 3-aminopropyltriethoxysilane (APTS) under a variety of conditions (pretreatment temperature = 200 °C for 200 series, or 110 °C for 110 series, 25 °C for RT series, or with silylation carried out in an aqueous slurry, AQ series).¹⁹ APTS-derivatization of the silica surface is of interest for such diverse applications as a variety of composite materials (in which APTS serves as a coupling agent between a silica-like component and, usually, an organic polymer) and for metal complexation agents. One sees from the spectra of Figure 5 that increasing the amount of water in the silylation process or increasing the postsilylation 'curing' temperature brings about changes in attached silane populations from species with

one Si-OSi attachment (-49 ppm) to species with two such attachments (-58 ppm) to three such attachments (-66 ppm). Although ^{13}C spectra are primarily useful for monitoring the residual $\text{Si-OCH}_2\text{CH}_3$ moieties in this system, a careful analysis of the ^{13}C CP MAS spectra of samples corresponding to those represented in Figure 5 reveals that the ^{13}C chemical shift of the central carbon of the pendant $-(\text{CH}_2)_3-$ group originating from APTS is sensitive to protonation or hydrogen bonding of the amino group. ^1H CRAMP spectra (vide infra) and ^{15}N CP MAS spectra are also useful for studying this important issue.

3.4 Fumed Silica

Other types of silicas (and derivatized silicas), besides those based on silica gels, have also been studied by ^{29}Si CP MAS (and DP MAS) experiments, e.g. by Brinker and co-workers^{20,21} and by Legrand and co-workers.^{22,23} Figure 6 shows a comparison of ^{29}Si CP MAS spectra of a fumed silica (a Cab-O-Sil, formed by the vapor-phase combustion of SiCl_4) and a silica gel equilibrated to about the same H_2O vapor pressure.²⁴ The same peaks are present, but they are broader in the case of the fumed silica, and the percentage of surface silica sites that are single silanols is seen to be smaller for the fumed silica than for silica gel. The greater linewidth presumably relates to the greater dispersion of local surface geometries (and chemical shifts) in the Cab-O-Sil structure, which is formed at a higher temperature, and possibly to

Figure 6 ^{29}Si CP MAS spectra of (a) Cab-O-Sil fumed silica and (b) silica gel. Top: experimental spectra. Bottom: individual Q_2 , Q_3 , and Q_4 peaks by deconvolution. Middle: computer sum of the contributions shown at the bottom. (Taken from Liu and Maciel²⁴)

Figure 7 ^{29}Si CP MAS spectra of polysiloxane polymer prepared from $\text{Si}(\text{OEt})_4$ and $(\text{CH}_3\text{O})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{Cl}$ with (a) $\text{Bu}_2\text{Sn}(\text{OAc})_2$ or (b) 0.1 M HCl as catalyst. (Taken from Elnahhal et al.²⁶)

the potential effects of so-called ‘interparticle sites’ at the junctures of the primary particles that contribute to the overall topography of a fumed silica.²³ Detailed studies of ^{29}Si CP MAS spin dynamics of fumed silicas, especially when viewed in relationship to analogous silica gel results, appear promising for identifying the main similarities and differences between these two types of silica surfaces.²⁴

3.5 Polysiloxane Systems

There has been a great deal of interest recently in a class of polysiloxane polymers prepared by the hydrolysis

and gelation of mixtures of reagents of the types, $\text{Si}(\text{OR}')_4$ and $\text{RSi}(\text{OR}'')_3$, where R' and R'' are typically methyl or ethyl and R is a ‘pendant’ group that contains some desired chemical moiety, e.g. a specific ligand.²⁵ By varying the nature of R and the ratios of the two types of starting reagents, a wide range of polysiloxane materials, with a broad variety of potentially useful properties, can be prepared. These polysiloxane materials bear a substantial similarity to derivatized (silylated) silicas, with a silica-like three-dimensional network to which the pendant (R) groups are attached. Hence, the NMR techniques that are useful for characterizing derivatized silicas are also useful for these polysiloxane systems.

Figure 7 shows ^{29}Si CP MAS spectra of polysiloxane systems with $-\text{CH}_2\text{CH}_2\text{CH}_2\text{Cl}$ as the pendant group, prepared by the reaction of $\text{Si}(\text{OEt})_4$ with $(\text{MeO})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{Cl}$, using two different catalysts.²⁶ One notes substantially different intensity ratios for the Q_2 , Q_3 , and Q_4 peaks in the two spectra [and possibly a Q_1 peak at about -82 ppm in Figure 7(b)], and for the peaks due to the pendant groups (at about 60 and 65 ppm), as well as a dramatic difference in intensities between the 60 and 65 ppm peaks relative to the Q_2 , Q_3 , Q_4 peaks, for the products from the two catalyst systems employed.

4 $^1\text{H} \rightarrow ^{17}\text{O}$ CROSS POLARIZATION

In addition to cross polarization to ^{29}Si in silica, or to ^{13}C (or ^{15}N , ^{31}P , etc.) in derivatized silicas, cross polarization to ^{17}O in isotopically-enriched silicas has also been illuminating. Oldfield and co-workers have during the past several years made significant progress in the application of solid state ^{17}O NMR techniques for the characterization of inorganic materials. Walter, Turner, and Oldfield²⁷ have demonstrated that $^1\text{H} \rightarrow ^{17}\text{O}$ CP experiments are not only feasible, but they are also very informative from the point of view of *editing* ^{17}O spectra, by discriminating against ^{17}O signals from oxygen sites with no directly bonded hydrogen. Figure 8 shows $^1\text{H} \rightarrow ^{17}\text{O}$ CP spectra of amorphous silica and a model SiOH system. From a comparison of the spectra obtained from static samples and by MAS, with and without CP, it was possible to assign the ^{17}O signal due to SiOH groups at the surface.

5 PROTON NMR APPROACHES

5.1 Dipole–Dipole Broadening

High-resolution ^1H NMR spectroscopy has proved to be highly useful in studying the surfaces of silicas and a variety of other solids. In order to obtain high-resolution ^1H NMR spectra of solids (including their surfaces), it is necessary to average not only the chemical shift anisotropy (easily done by MAS), but also ^1H – ^1H dipolar interactions.^{28,29} The latter can be very large (tens of kHz). Magnetic dipole–dipole interactions manifest an inverse cube dependence on internuclear distance. Therefore such interactions, and the ^1H – ^1H spin–spin flip-flops that they can generate, are especially strong if the protons are situated in close proximity to each other, e.g. in a typical organic solid, but also perhaps in hydrogen-bonded clusters of hydroxy groups on a surface. Hence, a priori one can feel confident that moderate-speed MAS experiments (say, less

Figure 8 Static and MAS ^{17}O spectra of amorphous SiO_2 and polycrystalline $(\text{C}_6\text{H}_5)_3\text{SiOH}$ obtained at 67.8 MHz. (a) ^1H -decoupled static spectrum of SiO_2 without CP: 108 scans. (b) ^1H -decoupled MAS spectrum: 100 scans, 7.6 kHz spinning speed (*indicates spinning sidebands). (c) $^1\text{H} \rightarrow ^{17}\text{O}$ static spectrum of SiO_2 , 200 scans, 0.1 ms contact time. (d) $^1\text{H} \rightarrow ^{17}\text{O}$ MAS spectrum of SiO_2 , 200 scans, 0.1 ms contact time. (e) ^1H -decoupled static spectrum of $(\text{C}_6\text{H}_5)_3\text{SiOH}$ without CP: 500 scans. (f) ^1H -decoupled MAS spectrum of $(\text{C}_6\text{H}_5)_3\text{SiOH}$: 800 scans, 4.0 kHz spinning speed. All spectra were obtained using a 2 s recycle time. (Taken from Walter et al.²⁷)

Figure 9 The multiple pulse line-narrowing strategy for averaging homonuclear dipolar interactions. Each rectangle [between (a) and (b)] represents one multiple pulse cycle (e.g. four pulses for WAHUA, eight for MREV-8 or 24 for BR-24). There is one data acquisition point for each cycle (e.g. between each rectangle). (Taken from Maciel⁵)

than 20 kHz) are adequate for studying silica surfaces only for substantially dehydrated samples. For nondehydrated or nondeuterated samples, in which the *local* surface density of protons can be substantial, multiple pulse techniques may be required for eliminating the line-broadening effects of ^1H - ^1H dipolar interactions. Alternatively, a useful strategy employed by Vega and co-workers is to ensure that the ^1H concentration is small by exchanging protons at the surface with deuterons.³⁰

5.2 Multiple Pulse Line Narrowing: CRAMPS

In 1968, Waugh and co-workers³¹ introduced a *multiple pulse* approach for averaging strong homonuclear dipolar interactions. The strategy of this kind of approach is that, over the *entire* period of each individual multiple pulse cycle (four 90° pulses in the original work), the average Hamiltonian that governs the evolution of the spins over the entire cycle does not include the homonuclear dipolar interaction. A nonvanishing chemical shift effect, albeit scaled down, is present in the average Hamiltonian. Hence, if one acquires one data point stroboscopically between each adjacent pair of multiple pulse cycles in a long string of such cycles, the resulting time-dependent signal (analogous to a free induction decay) is

Figure 10 ^1H NMR spectra of citric acid. (a) Static sample, single pulse, (b),(c),(d) MAS-only with indicated MAS speed. (e) and (f) CRAMPS. (Taken from Dec et al.³⁵)

modulated by chemical shift effects, but not by homonuclear dipolar effects. The strategy is outlined in Figure 9 in which each rectangle represents a multiple pulse cycle and each asterisk represents a data acquisition point. The bandwidth of the experiment depends on $1/t_c$, the inverse of the multiple pulse cycle time.

The original homonuclear line-narrowing pulse sequence (WAHUA)³¹ was a four pulse sequence; later elaborations involve more pulses in the total cycle and offer compensation for pulse imperfections and/or higher order averaging of the homonuclear dipolar interaction.^{32,33} In general, this class of experiments requires short ($<1.5\mu\text{s}$), powerful 90° pulses with precisely defined phases and until recently has been technically one of the most difficult experiments in the solid state NMR laboratory. Currently, the most popular multiple pulse sequences are the eight pulse MREV-8 sequence³² and the 24 pulse BR-24 sequence.³³

For powdered or amorphous samples, in order to avoid line broadening due to chemical shift anisotropy, magic angle spinning is employed (which also averages various heteronuclear dipolar couplings). Gerstein and co-workers³⁴ were the first to combine a multiple pulse homonuclear

Figure 11 ^1H NMR spectra of untreated silica gel. (a) Static sample, single pulse. (b),(c),(d) MAS-only with indicated MAS speed. (e) CRAMPS. (f) CRAMPS on an expanded scale. (Taken from Dec et al.³⁵)

line-narrowing technique with magic angle spinning, and introduced the acronym CRAMPS for Combined Rotation And Multiple-Pulse Spectroscopy.^{28,29}

5.3 ^1H CRAMPS Studies of Silicas

Figures 10 and 11 show the difference in ^1H line-narrowing capabilities between CRAMPS and MAS-only (no multiple pulse sequence) with a modestly high MAS speed (10–11 kHz).³⁵ For powdered crystalline citric acid (Figure 10), one sees six distinctly resolved ^1H CRAMPS peaks, but essentially no resolution in the 10.7 kHz MAS-only ^1H spectrum. This difference reflects the high proton concentration (~ 29 atom %) and molecular rigidity of crystalline citric acid. For the more proton-dilute (~ 2.5 atom %) silica gel system (Figure 11), the ^1H NMR experiment yields a modestly narrowed ^1H spectrum even on a static sample, and 4.7 kHz MAS yields a spectrum that is superficially similar to that obtained by CRAMPS. However, close inspection reveals important details that differentiate the ^1H spectra obtained by these two techniques [Figure 11(d) and (e)]. All of the remaining ^1H spectra discussed in this article were obtained by the CRAMPS technique.

One should note that the CRAMPS technique is not necessarily a panacea for ^1H NMR studies on surfaces, or for any other type of sample. Dynamics associated with motion and/or chemical reactions with a time constant that is comparable to the cycle time (t_c) of the multiple pulse sequence interferes with the multiple pulse averaging of

^1H – ^1H dipolar interactions.^{29,36} Of course, an analogous problem can also arise with magic angle spinning, for which the critical period is ν_{MAS}^{-1} , where ν_{MAS} is the MAS frequency.³⁷ To quench this kind of dynamic interference with the line-narrowing efficiency of any cyclic technique, like MAS and/or a multiple pulse sequence, one can try to alter the dynamics, e.g. by changing (usually lowering) the sample temperature.

As an example of the application of the ^1H CRAMPS technique to the study of silica surfaces,³⁸ Figure 12 shows the ^1H CRAMPS spectra obtained on untreated [Figure 12(a), (a'), (a'')] and dried [Figure 12(b), (c), (d)] silica gel samples. Comparison of spectra (a) and (b) show that the relatively sharp peak at about 3 ppm in the spectrum of an untreated silica is removed by moderate dehydration; this peak is therefore identified as physisorbed water. The broad nonsymmetrical peak that is largely to the left of the sharp 1.9 ppm peak is unaffected by sample evacuation at 200 °C, but removed by evacuation at 500 °C; this behavior suggests that this peak can be identified tentatively with clustered (or hydrogen bonded) silanols, which are close enough together that suitable dehydration pathways are available. The sharp peak at 1.9 ppm remains after evacuation at 500 °C; this behavior implies that the silanol groups represented by this peak are sufficiently far from each other to make dehydration difficult, so it is assigned to isolated (non-hydrogen-bonded) silanols. These assignments are consistent with 35 years of literature results on liquid solution samples, which show that hydrogen bonding typically reduces proton shielding, and with the reasonable point of view that a wide range of hydrogen-bonding structures exist on a silica surface (chemical shift dispersion:broad peak). These assignments are also consistent with the results of proton dipolar-dephasing experiments, as shown in Figure 13.

5.4 CRAMPS-Based Time Domain Studies of Silicas

Figure 13(a) shows a ^1H CRAMPS version³⁸ of the popular 'dipolar-dephasing' experiment used routinely in ^{13}C CP MAS NMR. In this ^1H CRAMPS version, a 'dephasing period' 2τ is inserted between the initial $\pi/2$ pulse that generates transverse magnetization and the multiple pulse line-narrowing pulse train that detects the transverse magnetization. During the dephasing period, those proton magnetic moments that experience strong dipolar interactions undergo a corresponding degree of dephasing, and the resulting detected signal will be accordingly attenuated. Figure 13(b) and (c) show the results of applying the dipolar-dephasing CRAMPS experiment to untreated silica gel [Figure 13(b)] and to a silica gel sample evacuated at 200 °C [Figure 13(c)]; in both cases one sees that the broad (3.0 ppm) peak is attenuated by a dephasing period (2τ) of 160 μs , whereas the sharp (1.7 ppm) peak is largely unattenuated. From the relationship between hydrogen bonding and proximity (between atoms that participate in a hydrogen bond) and the r^{-3} dependence of dipolar interactions, this dipolar-dephasing behavior provides strong support for identifying the 1.7 ppm peak as arising from isolated (non-hydrogen-bonded) silanols and the broad 3.0 ppm peak as clustered (hydrogen bonded) silanols. This is the same conclusion regarding proximity (and hydrogen bonding) that one would reach from the dehydration behavior shown in Figure 12. It would be difficult to rationalize the elimination

Figure 12 187-MHz ^1H CRAMPS spectra of Fisher S-679 silica gel. (a) untreated; (b) evacuated at 25 °C; (c) evacuated at 200 °C; (d) evacuated at 500 °C; (a'') deconvolution of spectrum (a); (a') computer simulation based on (a''). (Taken from Bronnimann et al.³⁸)

Figure 13 ^1H CRAMPS dipolar-dephasing experiment. (a) Pulse sequence. (b) results for untreated silica gel (showing τ values). (c) Results for sample evacuated at 200°C (showing τ values). (Taken from Bronnimann et al.³⁸)

of water via the ‘dehydration’ of silanols that are *isolated* from each other. Since the physisorbed water peak (3.5 ppm) is only slightly attenuated by the $160\ \mu\text{s}$ dephasing period [Figure 13(b)], one can conclude that water protons experience only weak resultant dipolar interactions, the result of efficient motional averaging.

Other CRAMPS-based ^1H time domain approaches have also been useful in studying silica surfaces. Figure 14 summarizes a CRAMPS-detected T_1^{H} determination on silica gel samples, based on an alternating, two-sequence scheme of the Freeman–Hill type.³⁹ One sees that for each of the two silica samples, untreated (b) and dried (c), all components of proton magnetization relax essentially homogeneously, which suggests that proton spin diffusion among the different spin isochromats is much more efficient than spin–lattice relaxation, which is characterized overall by T_1^{H} values of 0.7–4 s. Furthermore, the marked increase in T_1^{H} that results from sample drying indicates that the physisorbed water in the sample of Figure 14(b) provides an important relaxation source, and is presumably in a rapid state of motion at room temperature.³⁶ Having the ability to establish, via dipolar dephasing, different spin polarizations for hydrogen bonded

Figure 14 ^1H CRAMPS T_1 determination. (a) Pulse sequence, showing individual sequences employed in alternate scans (lower case subtracted from upper case in computer memory). (b) Results for untreated silica gel (showing τ values). (c) Results for sample evacuated at 25°C . (Taken from Bronnimann et al.³⁸)

and isolated silanols, one can explore spin exchange between these two spin sets by an experiment of the type shown in Figure 15(a).³⁸ One sees for the untreated silica [Figure 15(b)] that in a mixing time of a few ms after eliminating ^1H magnetization due to hydrogen-bonded silanols there is a substantial transfer of magnetization (spin exchange) from the isolated silanol reservoir to the hydrogen-bonded silanol protons. In any attempt to interpret or model the structure of the silica surface, the rate of this spin exchange places constraints on the spatial proximities of these two proton spin sets in terms of the dipole–dipole interactions that can be responsible for ^1H – ^1H flip-flops, and/or chemical (H^+) exchange.

Figure 15 ^1H CRAMPS spin exchange experiment. (a) Pulse sequence. (b) Results for untreated silica gel (showing τ_{mix} values). (c) Results for sample evacuated at 200°C (showing τ_{mix} values). (Taken from Bronnimann et al.³⁸)

A variety of CRAMPS-based ^1H NMR experiments of the types represented in Figures 12, 13, 14, and 15 have been carried out on silica samples in which there have been systematic variations of physisorbed water content or dehydration, and often temperature. Figure 16 shows ^1H CRAMPS dipolar-dephasing results obtained at room temperature on three different silica gels.³⁶ The behavior shown is consistent with the ideas described above. Figure 17 shows ^1H CRAMPS spectra of a hydrated (exposed to air) silica gel over a temperature range from 138 K to 298 K.³⁶ An effective freezing point depression of about 45 K can be noted from these kinds of measurements; this result is consistent with previous reports based on other types of experiments.⁴¹

Figure 16 ^1H CRAMPS dipolar-dephasing spectra of three different silica gels. (a) Untreated. (b) Modestly dehydrated (2.6% weight loss). (c) Drastically dehydrated (at 500°C)

5.5 Derivatized Silicas

Figures 18 and 19 show ^1H CRAMPS spectra of silica surfaces that have been derivatized with $(\text{CH}_3)_3\text{SiCl}$ and

Figure 17 ^1H CRAMPS spectrum of an untreated silica gel as a function of temperature, as shown

$(\text{CH}_3\text{CH}_2\text{O})_3\text{SiCH}_2\text{CH}_2\text{CH}_2\text{NH}_2$ (APTS), respectively. These spectra show that this technique can provide a rich level of structural detail on derivatized silica samples. The difference between the spectra of unprotonated and protonated APTS-derivatized samples (Figure 19) is the absence and presence, respectively, of a clearly distinct peak corresponding to the amino group of APTS.²⁹ This difference reflects, at least in part, the interference of ^{14}N quadrupole effects of the $-\text{NH}_2$ group with MAS averaging of ^1H – ^{14}N dipolar interactions. Calculations on $=\text{N}$ – H groups show that, because of the small internuclear N–H distances for directly bonded pairs, very high NMR fields (>1000 MHz) would be required to reduce this broadening to an acceptable level by the ‘brute force’ approach of simply going to a higher field.⁴²

6 CORRELATING ^1H -BASED AND ^{29}Si -BASED INFORMATION

6.1 Complementary Results

While one can distinguish between hydrogen bonded and isolated silanols by ^1H CRAMPS experiments and between single silanols and geminal silanols by ^{29}Si CP MAS experiments, it is important to correlate these two types of information. Ideally, one would base such a correlation on two-dimensional (2D) ^1H – ^{29}Si heteronuclear chemical shift

Figure 18 ^1H CRAMPS spectrum of trimethylsilyl-derivatized silica gel

Figure 19 ^1H CRAMPS spectra of APTS-modified silica gel. Lower, untreated. Upper, treated with HCl. (Taken from Maciel et al.²⁹)

correlation (HETCOR) experiments of the general type that are employed routinely for ^1H – ^{13}C correlation in liquids and more recently in solids.^{43,44} Indeed, Vega has reported such experiments based on $^1\text{H} \rightarrow ^{29}\text{Si}$ CP for the polarization transfer step.⁴⁵ However, as is seen below, rotating frame ^1H spin diffusion among the protons in a typical silica gel during the spin lock state in a $^1\text{H} \rightarrow ^{29}\text{Si}$ CP experiment can substantially scramble what one would hope are discrete $\text{H} \leftrightarrow ^{29}\text{Si}$ CP correlations in the time frame ($>200 \mu\text{s}$) required for relatively efficient CP transfer. Furthermore, the multiple

Figure 20 Proton-decoupled (top spectrum of each set) and proton-coupled (bottom spectrum of each set) 39.75 MHz ^{29}Si CP MAS NMR spectra of Fisher S-679 silica gel at six different magic angle spinning speeds. Cross polarization time, 5 ms. (a) 1.0 kHz, 1096 accumulations (b) 1.1 kHz, 3000 accumulations (c) 1.4 kHz, 720 accumulations (d) 1.6 kHz, 2000 accumulations (e) 1.8 kHz, 2000 accumulations (f) 2.0 kHz, 2000 accumulations. (Taken from Chuang et al.⁴⁷)

pulse approaches used in ^1H - ^{13}C HETCOR experiments on solids are not very efficient in these ^1H - ^{29}Si systems, although recently reported successes in ^1H - ^{31}P 2D HETCOR experiments on P-O-H systems⁴⁶ indicate that ^1H - ^{29}Si HETCOR in silica may be attractive. In any case, as an alternative to the 2D HETCOR approach, a variety of ^{29}Si -detected ^1H - ^{29}Si CP experiments have been carried out, in which the behavior of protons is monitored by ^{29}Si , establishing the correlation.⁴⁷

6.2 ^{29}Si Detection of Proton Spin Behavior

The simplest such experiment is a ^{29}Si CP MAS experiment in which ^{29}Si detection is carried out *without* proton decoupling. MAS should still average the ^1H - ^{29}Si dipolar interaction during detection, yielding a corresponding sideband pattern to the extent that this interaction behaves inhomogeneously, i.e. to the extent that the ^1H - ^{29}Si dipolar interaction is not altered (by chemical reaction, motion, or ^1H - ^1H flip-flops) during a MAS rotor period.⁴⁷ Figure 20 shows a comparison of spectra obtained with and without ^1H decoupling; it is

clear that the geminal silanol peak suffers most dramatically from the absence of high-power ^1H decoupling, implying that ^1H spin exchange is most efficient in the protons of geminal silanols.

Another ^{29}Si CP MAS experiment useful for correlating ^1H and ^{29}Si spin behaviors is the ^1H - ^{29}Si analog of the common ^1H - ^{13}C dipolar-dephasing experiment. In this technique, rotational and Hahn echo formation occur for a dephasing period (2τ) corresponding to two MAS rotor periods ($2\tau_{\text{rot}}$) for the isotropic ^{29}Si chemical shift, the ^{29}Si chemical shift anisotropy, and the ^1H - ^{29}Si dipolar interaction (to the extent that it behaves inhomogeneously).⁴⁷ Figure 21 shows results of the ^1H - ^{29}Si dipolar-dephasing ^{29}Si CP MAS experiment with the dephasing period ranging over more than $4\tau_{\text{rot}}$. Focusing on the points at $2\tau = 0$, $2\tau_{\text{rot}}$ and $4\tau_{\text{rot}}$, one sees very little dephasing decay for the Q_4 (siloxane) signal, and more efficient decay for the Q_2 (geminal silanol) signal than for the Q_3 (single silanol) signal. This again suggests more efficient ^1H - ^1H spin diffusion among the $=\text{Si}(\text{OH})_2$ protons than among SiOH protons.

A very direct correlation of ^1H CRAMPS dipolar-dephasing behavior with ^{29}Si CP MAS signals is obtained in the experiment shown in Figure 22, in which there is a 2τ ^1H - ^1H

Figure 21 Plots of deconvoluted peak integrals of the 39.75-MHz ^{29}Si CP MAS NMR spectra of Fisher S-679 silica gel versus ^1H - ^{29}Si dipolar-dephasing time up to four rotor periods. CP contact time, 5 ms; magic angle spinning speed, 2.0 kHz. Vertical dashed lines show odd numbers of rotor periods and vertical solid lines show even numbers of rotor periods. (a) -89 ppm peak (geminal silanols); (b) -99 ppm peak (single silanols); (c) -109 ppm peak (siloxane silicons). (Taken from Chuang et al.⁴⁷)

dipolar-dephasing period *before* CP transfer to ^{29}Si .⁴⁷ Taking account of the rotational echo behavior of ^1H magnetization, for $2\tau = 2nt_{\text{rot}}$ essentially all relevant proton interactions refocus except the ^1H - ^1H dipolar interaction. Hence, the magnetization of those protons involved in the strongest (shortest, least mobile) hydrogen bonds is most effectively dephased during $2\tau = 2nt_{\text{rot}}$ and unavailable for CP transfer to ^{29}Si . Figure 23 shows the results obtained on a silica gel sample. For a CP contact time (t_{cp}) that is small enough ($100 \mu\text{s}$) to avoid the rotating frame spin diffusion that scrambles the desired ^1H - ^{29}Si correlation (vide supra), the geminal silanol peak at -89 ppm is the one that suffers most from ^1H - ^1H dipolar dephasing for a $2t_{\text{rot}}$ period. The effect of rotating frame proton spin diffusion is also clear from the spectra in Figure 23: if a long CP contact period (e.g. 1–5 ms) is employed, essentially the same relative peak intensities are

Figure 22 ^{29}Si CP MAS NMR experiment with ^1H - ^1H dipolar-dephasing prior to $^1\text{H} \rightarrow ^{29}\text{Si}$ cross polarization. (Taken from Chuang et al.⁴⁷)

Figure 23 ^{29}Si CP MAS NMR spectra of Fisher S-679 silica gel obtained with $2 \mu\text{s}$ (top spectrum of each set) and two rotor periods (1.04 ms; bottom spectrum of each set) of ^1H - ^1H dipolar-dephasing prior to four different ^1H - ^{29}Si CP contact times. Magic angle spinning speed, 1.9 kHz. (a) $t_{\text{cp}} = 100 \mu\text{s}$ (top spectrum, 7376 accumulations; bottom spectrum, 82 504 accumulations); (b) $t_{\text{cp}} = 300 \mu\text{s}$ (top spectrum, 2400 accumulations; bottom spectrum, 46 200 accumulations); (c) $t_{\text{cp}} = 1 \text{ ms}$ (top spectrum, 432 accumulations; bottom spectrum, 21 232 accumulations); (d) $t_{\text{cp}} = 5 \text{ ms}$ (top spectrum, 600 accumulations; bottom spectrum, 8320 accumulations). (Taken from Chuang et al.⁴⁷)

obtained whether or not the $2t_{\text{rot}}$ ^1H - ^1H dipolar-dephasing period is included in the experimental sequence.

One overriding theme emerges from all the results embodied in Figures 20–23: the protons that are primarily responsible for cross polarization to geminal silanol silicons are much more extensively involved in hydrogen bonding than are the protons primarily responsible for cross polarization to single silanol silicons. This theme is consistent with structural models of the

Figure 24 Side views of specific silicon planes (dashed line representing an edge of such a plane) of β -cristobalite. Drawing approximately to scale: (a) 111 face; (b) 100 face; (c) vicinal sites from dehydration of the 100 face. (Taken from Chuang et al.⁴⁷)

silica surface (or, at least fragments of it) that correspond to specific faces of a β -cristobalite crystal.^{47,48}

Figure 24 shows views looking 'into' the 111 and 100 faces, which contain single silanols (Q_3) and geminal silanols (Q_2), respectively. From the O–O distances between hydroxyl oxygens of these surfaces, we see that one should expect hydrogen bonding between adjacent geminal silanols, but not between adjacent single silanols; this is in agreement with the NMR results summarized above. Of course, the silica surface is not a homogeneous one, and may be describable as a composite of these two types of surfaces, with suitable interfaces. The geometrical relationship between silanols that are adjacent *across* these interfaces is important in the overall hydrogen-bonding patterns at silica surfaces. Furthermore, the presence of water on the surface dramatically changes the pattern of hydrogen bonding, including the establishment of hydrogen-bonding networks among the single silanols.

7 SUBSURFACE SILANOLS

An implicit assumption on which the use of ^{29}Si CP MAS as a kind of surface-selective technique is based is the following: essentially all (or at least most) of the protons of a sample like SiO_2 are at the surface. This assumption has been tested in a variety of ways, including ^{29}Si NMR. One NMR avenue for testing this assumption is to examine the ^1H and/or ^{29}Si

Figure 25 ^{29}Si CP MAS spectra of silica gels stirred in H_2O or D_2O at 25°C or 100°C , as indicated

NMR spectra of samples that have been subjected to repeated exchanges with D_2O . Figure 25 shows the ^{29}Si CP MAS spectra of silica gel samples that have been treated in this way.⁴⁰ From such studies, it has been determined that for a typical silica gel, 91–97% of the silanols are exchangeable with D_2O , the exact percentage depending on the time and temperature of the exchange. The geminal silanol signal is completely depleted by D_2O exchange, and Figure 26 shows that this signal is immediately restored to its equilibrium intensity shortly after a D_2O -exchanged silica is exposed to the moisture in air. Hence, none of the inaccessible or subsurface silanols are of the Q_2 type.

Extensive studies of spin dynamics in D_2O -exchanged samples have revealed a substantial amount of detail about the local environment and motional dynamics of 'internal' silanols in silica gel.⁴⁰ The T_{HSi} values indicate that the hydroxy groups of 'internal' silanols rotate freely about the Si–O axis in a manner similar to the rotation of non-hydrogen-bonded silanols on a dehydrated silica surface. Analogous studies have also been carried out on a fumed silica Cab-O-Sil.²⁴ While the D_2O -exchange behavior and various features of ^1H and ^{29}Si spin dynamics in Cab-O-Sil are qualitatively similar to what is discussed above for silica gel, some significant and possibly important differences are observed,²⁴ perhaps because of interparticle (particle bridging) silanols that have been suggested by some authors for fumed silicas.

8 SUMMARY AND CONCLUSIONS

MAS NMR approaches based on ^1H and ^{29}Si are enormously useful in the characterization of silica surfaces, including derivatized silica surfaces. The CRAMPS technique, and especially dipolar-dephasing elaborations, provide a powerful way to distinguish between hydrogen bonding and isolated silanols. Silicon-29 CP MAS spectra clearly distinguish between Q_2 , Q_3 , and Q_4 sites at the surface. Via $^1\text{H} \rightarrow ^{29}\text{Si}$ cross polarization, the ^{29}Si CP MAS technique provides avenues for projecting ^1H spin behavior onto a ^{29}Si NMR spectrum. D_2O -exchange approaches allow the use of ^1H and ^{29}Si NMR behavior to examine subsurface or trapped silanols.

1 INTRODUCTION

1.1 Biomineralization: Background and Significance

Biomineralization, defined as the organized deposition of inorganic materials in the cellular or extracellular matrix, may be as simple a process as the formation of an iron oxide crystal in the vesicle of a magnetobacterium, or as complex a process as the formation of the intricate calcium carbonate and calcium phosphate structures found in marine coccoliths, invertebrate shells, vertebrate skeletons and teeth. The phenomenon of biomineralization has attracted a great deal of attention recently from the materials science community, which seeks to understand the way in which inorganic biological composites are synthesized and processed in nature.^{1–8}

An extremely important problem in the field of biomineralization is understanding the manner in which mineral deposition is controlled *in vivo*. The crystal engineering processes necessary to achieve the controlled deposition of minerals at physiological temperatures and in aqueous solutions are directly provided by proteins in most known examples.^{7,9–17} In particular, the deposition of minerals in most hard tissues in higher organisms is controlled by a class of unusually acidic, non-collagenous proteins and glycoproteins.^{9,10,17,21–28} These acidic proteins typically comprise only about 1% of the mass of the organic matrix, and are frequently found sandwiched between crystal surfaces and major framework molecules like collagen or chitin. They are rich in acidic amino acids including aspartic and glutamic acid, and contain large numbers of phosphorylated amino acids, especially phosphoserine.

In the specific case of hydroxyapatite ($\text{Ca}_{10}(\text{PO}_4)_6(\text{OH})_2$), the principal mineral component of bone and dental enamel, extra-cellular, acidic, non-collagenous proteins include apatite nucleators like bone sialoprotein, osteonectin, and dentin phosphoryn, while osteocalcin, osteopontin, and salivary statherin inhibit apatite formation and growth. In some cases (e.g.,

osteonectin, bone sialoprotein, and dentin phosphoryn) apatite formation is inhibited at high protein concentration while nucleation of apatite occurs at low protein concentration.

Substantial progress has been made in recent years in characterizing, at the macroscopic level, the structural properties of biological composites,^{1,18–20} but there is still a significant gap in our understanding of the molecular recognition processes underlying acidic protein-calcium composite interactions. In particular, while protein model structures have been proposed which hypothesize the involvement of protein secondary structure motifs for presentation of carboxylate residues,^{10,13,26,28,29} the lack of high resolution structural data for proteins on surfaces precluded any molecular structure vs. function studies.

The acquisition of molecular-level structural information for proteins on surfaces is not only important to the field of biomineralization but has broad applicability in a number of important fields. For example, there is currently a great deal of effort in the fields of drug delivery, implant design, tissue engineering, and diagnostics directed toward developing polymeric surfaces for immobilization and controlled release of peptides and proteins. Detailed structural information about proteins bound to material surfaces will provide important new design criteria from the perspective of peptide/protein structure, dynamics, and assembly at polymeric biomaterial surfaces.

1.2 The Role of Protein-Crystal Interactions in Biomineralization

Understanding the function of a biomineralization protein requires that the secondary and tertiary structure of the molecule be defined within its biological context, i.e. the protein in contact with the crystal. In addition, the precise nature of the interactions between the protein and the crystal which underlie the recognition process must be understood. This requires a knowledge of the contacts formed between the amino acid side chains of the protein and the ions in the crystal faces. The involvement of water molecules in these interactions must be understood as well.

Current investigations of protein-mineral interactions are commonly conducted with techniques that characterize the macroscopic behavior of proteins in the presence of mineral crystals. Equilibrium properties such as protein-crystal binding constants are derived via adsorption isotherm measurements, where data are analyzed usually by assuming a simple Langmuir model of protein adsorption onto the crystal faces. But the most commonly-used approach for determining protein-crystal interactions *in vitro* are kinetic experiments in which a small amount of protein is dissolved in a saturated solution of a particular inorganic salt and the time required for crystals to form is compared to a control solution in which no protein is present. Assays also exist for determining selective binding of a particular crystal face by a protein as well as oriented nucleation of crystals in the presence of acidic proteins.³⁰

However, to move beyond macroscopic aspects of protein-crystal interactions, what is clearly needed are high resolution spectroscopic methods that can provide information about the atomic level structure of the protein on the crystal face, under physical conditions that are biologically relevant (physiological levels of hydration and pH). Information about the secondary structural motifs that occur in the adsorbed protein together with information on the exposure of protein

side chains to the crystal face, may lead to an understanding of how particular proteins promote or inhibit nucleation. Analytical techniques currently used to probe protein-crystal interactions at the atomic and molecular levels and the advantages that solid state NMR bring to the field will be briefly reviewed in the next section.

2 NMR STRATEGIES FOR STUDYING SURFACE-ADSORBED PROTEINS

The lack of high resolution structural data for proteins on surfaces is the result of a lack of high resolution structural methods that can be brought to bear on relevant problems. The conventional methods of high resolution structural biology, X-ray crystallography and solution nuclear magnetic resonance (NMR) spectroscopy have provided information on a few biomineralization proteins in the pure crystalline and solution states,^{31–33} but both techniques are severely limited in their abilities to elucidate the structures of proteins on biomineral surfaces. Although traditional surface science methods like photo-electron spectroscopy and NEXAFS have provided important information on protein adsorbed onto planar surfaces, and, in particular, may be used to characterize the degree of long range ordering in systems of adsorbed proteins on polymer surfaces as well as average structural properties, these techniques have yet to provide detailed atomic-level structural information for surface-adsorbed proteins. In addition surface diffraction methods and many optical techniques are not applicable to proteins adsorbed onto porous surfaces (e.g., porous plastics) or to other surfaces which preclude long-range ordering.

To fully appreciate the utility of solid state NMR in the study of protein structure at biomaterial interfaces, it is first important to recognize the dual nature of the protein-surface problem. There is first the familiar structural aspect, alluded to briefly in the prior section, which includes defining the secondary and tertiary structures of the adsorbed protein and by implication any structural changes which occur upon binding to the surface. The structure and chemical composition of the crystal surface in contact with the protein side chains must also be understood. In addition, a less familiar but no less important aspect is the dynamics of the adsorbed protein. It is desirable that the protein be observed on the surface under biologically relevant conditions, i.e., fully hydrated. Dehydration of the sample may alter not only the structure of the protein from its biologically relevant form but may quench the dynamics of the protein on the surface. Here we refer to both whole-molecule dynamics describing the protein's rigid body kinematics on the surface and to internal dynamics wherein the protein's conformation may be labile on the NMR time scale. In the following section we will review how solid state NMR can be used to probe both molecular structure and dynamics on surfaces.

2.1 NMR Structural Methods for the Study of Protein Structure at Biomaterial Interfaces

Solid state NMR has long been used to identify and characterize the structures of small organic molecules adsorbed onto catalytic surfaces,^{34–36} argon matrices,³⁷ and silica surfaces.^{38–40} There similarly exist a number of solid state

NMR pulse techniques capable in principle of reporting the structures of surface-adsorbed proteins. The most straightforward approach is to evaluate the secondary structure of surface-adsorbed proteins from the chemical shifts of ^{13}C spins located in the protein backbone. This approach basically exploits the fact that the isotropic chemical shifts of the backbone carbonyl, α , and β ^{13}C spins of each amino acid residue are to varying extents sensitive to the local secondary structure of the protein. Although recent work by Oldfield and coworkers has placed structural interpretation of isotropic ^{13}C chemical shifts of proteins on a quantitative basis,^{41–43} in the past analyses of structures using chemical shift data have been applied empirically, i.e., by comparing experimentally observed ^{13}C chemical shifts for backbone ^{13}C spins to a large body of data, derived via ^{13}C Cross Polarization/Magic Angle Spinning (CPMAS) experiments from polypeptides of known secondary structure in the condensed state. An excellent example of this type of analysis is the seminal work by Fernandez et al.⁴⁴ who studied the structures of polyglutamic acid and polylysine adsorbed to hydroxyapatite and silica using ^{13}C CPMAS. In addition to studies of the conformations of polypeptides on apatite and silica surfaces, ^{13}C MAS has been used to study the incorporation of carbonate ions in bone and synthetic apatites,⁴⁵ and ^{31}P MAS has been used to characterize the structures of various calcium phosphates found in biological systems.^{46–48}

Isotropic chemical shift data can be supplemented by quantitative structural data obtained via orientational constraints and/or distance/torsion angle constraints. The best examples that illustrate the use of orientational constraints and distance/torsion angle constraints come from the membrane protein literature. Structural data on membrane-associated proteins have been acquired by two general types of solid state NMR data: (1) orientational constraints, usually obtained from magnetic interaction tensors located in the backbone of proteins oriented in mono-domain lipid bilayers; and (2) distance and torsion angle constraints acquired from proteins associated with unaligned lipid vesicles. The former class of experiment requires the application of local field spectroscopy techniques (e.g., PISEMA) to oriented samples.⁴⁹ Although possible to achieve with lipids, there is no general analog in biomaterial interfaces to the mono-domain bilayer construct, so the orientational constraint approach has yet to be applied to biomaterials. Because distance and torsion angle constraints are generally acquired from unoriented samples via homo- and heteronuclear dipolar recoupling experiments, this approach shows the greatest promise in studies of surface-adsorbed biopolymers.

There are a number of dipolar recoupling experiments currently used to address a variety of problems in the material and biological sciences. No attempt will be made here to comprehensively cover all the alternative methods, their relative advantages and disadvantages. The reader is referred to general review articles on the subject of dipolar recoupling for more extensive treatments of dipolar recoupling.^{50,51} The following discussion is provided simply to clarify some general properties of dipolar recoupling sequence referred to in descriptions of studies of surface-adsorbed proteins.

Solid state NMR spectra of spin 1/2 nuclei are dominated by two magnetic interactions, the chemical shift anisotropy (CSA) and the direct nuclear dipole-dipole interaction (Figure 1). As discussed above, the former interaction is valuable as a qualitative probe of protein structure. The dipole-dipole interaction

Figure 1 The dipolar coupling tensor is a uniaxial tensor. The principal axis frame of this dipolar tensor has a z axis parallel to the internuclear vector. The dipolar coupling is proportional to the inverse cube of the internuclear distance ($1/r^3$), and the second order Legendre polynomial $(3/2)\cos^2\theta - (1/2)$, where θ is the angle between the internuclear vector and the magnetic field. The solid state NMR spectrum of a pair of dipolar-coupled spin 1/2 nuclei with negligible CSA's should be a Pake powder pattern, from which the dipolar coupling constant may be easily extracted. However, if the coupled spin 1/2 nuclei have CSA's much larger than the dipolar coupling it will be difficult to extract the dipolar coupling constant from the NMR powder spectrum. The figure shows the powder spectrum of two dipolar coupled ^{13}C spins, each with a CSA on the order of 20 kHz; and with dipolar coupling of 500 Hz, corresponding to a ^{13}C pair separated by 2.5 Å. The spectrum is clearly dominated by the CSA and it is very difficult to discern the presence of a dipolar coupling in the spectral data

has a straightforward structural interpretation because the dipolar coupling constant is proportional to the inverse cube of the internuclear distance. However, in many systems composed of coupled spin 1/2 nuclei, the magnitude of the CSA may exceed the magnitude of the dipole-dipole interaction. For example, for two sp^2 hybridized, directly bonded ^{13}C spins the CSA's may approach 200 ppm, corresponding to over 20 000 Hz in a 9.4 Tesla magnetic field. On the other hand, the dipole-dipole interaction for this directly bonded spin pair will not exceed 2300 Hz, and may be even smaller for non-bonded ^{13}C spins. Therefore the dipolar coupling constant may not be easily discerned in spectral data when the CSA exceeds the dipolar interactions by orders of magnitude so it is necessary to use NMR methods which suppress one of these interactions thus enabling straightforward detection of the other.

In the late 1960s NMR coherent averaging experiments were introduced to remove the dipolar coupling between spin 1/2 nuclei (^{19}F , ^1H , etc.) in crystalline solids, while simultaneously preserving the chemical shift anisotropy (CSA).^{52,53} The spin dynamics that underlie these experiments have been thoroughly quantified with Average Hamiltonian Theory (AHT).^{54,55} Basically, homonuclear dipolar decoupling sequences like WHH-4,⁵³ MREV-8,⁵⁶ BR-24,⁵⁷ MSHOT-3⁵⁸ etc. exploit the different transformational properties of the chemical shift anisotropy (CSA) and the dipolar interaction in spin space to remove the homonuclear dipolar interaction while preserving a scaled CSA.

Physical rotation of the sample (i.e., Magic Angle Spinning,⁵⁹ MAS) coherently averages spatial parts spin interaction Hamiltonian that transform as second rank tensors. However, both the dipolar and the chemical shift Hamiltonians transform as second rank tensors in Cartesian space, so MAS removes

the effect of both interactions from solid-state NMR spectra. The objective of dipolar recoupling is to use MAS and radio frequency (rf) irradiation in synchrony, with the ultimate objective of suppressing the chemical shift while preserving the dipolar coupling. Because information on internuclear distances can be recovered using dipolar recoupling techniques, these pulse sequences are widely used in structural studies of molecular solids.

The two dipolar recoupling pulse sequences that will be discussed in the context of structural studies of proteins adsorbed at biomaterial interfaces are the heteronuclear recoupling experiment Rotational Echo Double Resonance (REDOR) and the homonuclear recoupling experiment Dipolar Recoupling with a Windowless Sequence⁶⁰ (DRAWS). REDOR, developed by Schaefer and coworkers has been reviewed elsewhere.⁶¹ We confine our remarks to stating that in studies of surface-adsorbed biopolymers REDOR has a number of uses including: (1) Direct characterization of the surface, as was done by Pan⁶² who used ^{31}P - ^{19}F REDOR to study the distribution of ^{19}F in fluoroapatite; (2) ^{13}C - ^{15}N REDOR to confirm helical secondary structures in surface-adsorbed proteins by measuring hydrogen bond lengths between the ^{13}C carbonyl spin of the i residue to the ^{15}N amide spin of the $i + 4$ residue; and (3) probing dipolar interactions from ^{13}C and ^{15}N spins in protein side chains to NMR-active spins in the surface, ^{31}P spins in hydroxyapatite and ^{19}F spins in fluoropolymers, for example.

DRAWS is well suited to measuring distances between backbone carbonyl carbons in peptides and proteins.^{63–66} Dipolar couplings of less than 40 Hz between carbonyl ^{13}C spins have been detected in biopolymers at high magnetic fields,^{67–70} attesting to the ability of DRAWS to suppress large CSAs and at the same time detect small dipolar couplings between non-bonded ^{13}C spins. Figure 2 shows three forms of the DRAWS dipolar recoupling pulse sequence. In the DRAWS experiment, the unit pulse cycle (Figure 2a) is applied synchronously with the sample spinning and thus the duration of the unit cycle is exactly equal to one rotor period τ_{rotor} . The DRAWS experiment, which utilizes a four step supercycle, shown in Figure 2(a), is commonly employed in the context of a CPMAS experiment, see Figure 2(a). The basic strategy is to detect the amplitude of transverse magnetization that remains after an integral number of DRAWS super-cycles. Repeating this measurement as a function of the number of DRAWS supercycles results in a “dephasing” curve (Figure 3). Simulation of this dephasing curve results in a value for the internuclear distance.

The DRAWS dephasing curve is a useful measurement for determining protein secondary structure because, as shown in Figure 3, the carbonyl-carbonyl distance is directly related to the Ramachandran torsion angle φ . Therefore, using DRAWS distance measurements, the torsion angle φ may be determined at several positions in a peptide in a model-independent fashion. An example of a DRAWS experiment applied to a crystalline tripeptide alanyl-glycyl-glycine (AGG), labeled at both carbonyl positions with ^{13}C , is shown in Figure 4. Agreement with the crystallographically determined φ of -83° is excellent. Additionally, DRAWS can also measure conformational heterogeneity since the dipolar recoupling efficiency is independent of any correlation between chemical shift and peptide secondary structure. This allows the determination of the distribution of peptide conformers in a given sample.

Figure 2 In most dipolar recoupling pulse sequences, pulsed irradiations are applied synchronously with the sample rotation. In DRAWS, the eight 360° pulses (alternating Y and $-Y$ phases) and two ninety degree pulses (X phases) that constitute the unit pulse cycle (R) are applied within a single period of the rotor (τ_{rotor}). (a) The unit pulse cycle for DRAWS (Dipolar Recoupling with a Windowless Sequence) is supercycled as RRRR, where $\bar{R}$ indicates a unit cycle phase-shifted by 180° . (b) DRAWS applied in the context of a CPMAS experiment. (c) Pulse Sequence for Doubled Quantum-filtered DRAWS. (d) Two dimensional pulse sequence for double quantum DRAWS (DQDRAWS)

DRAWS dephasing curve data may be difficult to quantify in terms of an internuclear distance if a large background signal occurs from ^{13}C spins at natural abundance. The ^{13}C background arises from portions of the protein that are not enriched with ^{13}C or may come from the surface itself if the mineral contains carbon (e.g., calcite) or if the mineral contains organic impurities (e.g., carbonate incorporated into apatite crystals). In such cases NMR signals arising from dipolar coupled spin pairs are separated from the natural abundance signal, which arises mainly from isolated spins, by filtering the DRAWS signal through a double quantum state. The preparation of double quantum coherence using DRAWS

dipolar recoupling is called DQDRAWS. The DQDRAWS filtering experiment is shown in Figure 2(c). Applying a DRAWS pulse sequence for a preparation time τ (typically 3–6 ms for carbonyl ^{13}C spins in the backbone of a surface-adsorbed protein) generates dipolar-correlated spin coherence (also called anti-phase magnetization). Applying a 90° pulse then generates double quantum coherence. In the double quantum buildup experiment, this coherence is immediately transferred back to anti-phase magnetization by a second 90° pulse and then to observable magnetization by reapplying the DRAWS mixing sequence for the same amount of time. The buildup of double quantum coherence is then monitored

Figure 3 Simulated DRAWS decay curves for dipolar-coupled ^{13}C - ^{13}C carbonyl spin pairs in the backbone of a polypeptide. The carbonyl-carbonyl distance is directly related to the Ramachandran angle φ

Figure 4 Experimental DRAWS dipolar dephasing curve obtained for the doubly carbonyl ^{13}C labeled crystalline tri-peptide alanyl-glycylglycine (AGG). The solid line is the simulation assuming a Ramachandran angle of -84°

as a function of the DRAWS mixing time to determine dipolar couplings and hence the inter-nuclear distance. As in the simple DRAWS experiment, the DQDRAWS filtering experiment can quantify the carbonyl-carbonyl distance and hence the Ramachandran angle φ .

Direct detection of a double quantum coherent state results in a simultaneous measurement of the (φ, ψ) Ramachandran angles.^{64,71} As in other multiple quantum experiments, a double quantum state is detected via a two dimensional

experiment, the pulse sequence is shown in Figure 2(d). In the 2-dimensional DQDRAWS experiment, the DRAWS pulse sequence is again applied for a preparation time τ to generate the antiphase state. After the magnetization is transferred to the double quantum state by a 90° pulse it is allowed to evolve under the chemical shift and dipolar interactions for a time t_1 . The magnetization is then transferred back to observable by a second 90° pulse and reapplying the DRAWS mixing sequence for the same amount of time. Monitoring the free induction decay (FID) during the detection time t_2 as a function of double quantum evolution time t_1 yields a two dimensional interferogram. Two dimensional Fourier transformation of the time domain data followed by projection onto the ω_1 axis (i.e. the double quantum frequency axis) yields the double quantum spectrum, see Figure 5. The double quantum spectrum consists of a “fundamental” frequency, which occurs at the sum of the isotropic chemical shift frequencies of the coupled ^{13}C spins, together with side bands at integral multiples of the spinning frequency. The double quantum spinning side band intensities are dependent on the principal values of the *sum* chemical shift tensor. Because the individual chemical shift tensors add as second order tensors, the sum tensor is sensitive to the mutual orientation of the principal axis systems of the CSA tensors of the coupled ^{13}C spins.

Since carbonyl carbons in peptides possess highly anisotropic CSAs, they are particularly sensitive to the DQDRAWS approach. The relative orientations of the carbonyl carbon CSAs to the peptide amide bonds are well-studied,⁷² and thus the torsion angles (φ, ψ) can be extracted by simulating the DQ spectrum. Determining (φ, ψ) with this level of accuracy not only yields secondary structure, but also gives some indication of helical pitch or twist and long range order.

Figure 5 Simulated and experimental projections of the two dimensional double quantum DRAWS (DQDRAWS) spectra of the doubly carbonyl ^{13}C labeled crystalline tri-peptide alanyl-glycylglycine (AGG). The simulation assumes $\varphi = -83^\circ$ and $\psi = 169^\circ$

2.2 The Effect of Dynamics on the Solid State NMR Spectrum of Surface-Adsorbed Proteins

A common property of polymers is structural deformability. Polymeric molecular systems may display structural heterogeneity, meaning the polymeric system may display a distribution of static structures. In addition, the polymer may display structural lability, meaning that the molecular system cannot be described as strictly confined to one or a small number of equilibrium states, but rather possesses a kinetic aspect wherein the structure of each molecule changes in time. In such cases important properties of the polymer include the time scale and amplitude of the internal molecular motions.

The interaction between two nuclear magnetic dipoles, the interaction between the nuclear quadrupole moment and surrounding electric field gradients, and the chemical shift, are inherently tensorial quantities. In addition, these interactions detectable by NMR have sufficient anisotropy to dominate the solid state NMR spectral line shape. If internal motions modulate the orientation of magnetic interaction tensors relative to the static magnetic field direction, the solid state NMR line shape will be averaged in a way that reflects both the amplitude and the time scale of the internal motions. In addition, the relaxation of the nuclear system will be described by the time-dependent part of the spin interaction Hamiltonian. For these reasons the dynamic properties of solid polymers are frequently probed through measurements of NMR relaxation and line shapes.

Solid state NMR studies of polymer dynamics constitute an extensive literature, which cannot be summarized here in any thorough way. However, it is useful to briefly review some of the important NMR methods used in the past to characterize polymer dynamics, including surface-adsorbed polymers, in order to appreciate how these methods may or may not suffice to characterize surfaced-adsorbed proteins.

The most extensive class of polymers studied to date by solid state NMR methods are synthetic, organic polymers common examples being polystyrene,⁷³ polycarbonate,^{74–76} polystyrene–polybutadiene blends,⁷⁷ poly(ethylene-terephthalate),^{78,79} to name just a very few. In addition there are numerous reports on liquid crystal polymers,^{80,81} polymers tethered to silica surfaces,³⁹ and polylysine and polyglutamic adsorbed to silica and hydroxyapatite surfaces.⁴⁴ In the case of hydrocarbon-based polymers the NMR dynamic probes are ¹³C relaxation and line shape studies, proton relaxation and spin diffusion studies. In cases where protons can be replaced by deuterium, deuterium line shape and relaxation studies may be used to probe polymer motions. Because synthetic polymers are composed of regularly repeating, largely identical subunits, isotopic enrichment usually cannot be performed in a site selective manner. This means that NMR studies of polymer dynamics reflect motions that are associated with a repeating unit, or a part of the repeating unit.

Many of the problems and questions in biomineralization are similar to the structure/function issues familiar in structural biology and concentrate on specific domains within the protein: e.g., what is the identity, structure and dynamics of the mineral binding surface of the protein, what is the relationship of this binding domain to the rest of the protein, and how are the structure and dynamics of this domain related to the function? This latter question can only be answered if the orientation of the protein relative to the surface is known. These questions can only be addressed by studying the NMR line shapes and

relaxation of specific sites within the protein, before and after adsorption.

3 A SOLID-STATE NMR STUDY OF SALIVARY STATHERIN ADSORBED ONTO HYDROXYAPATITE (HAP) CRYSTALS

Salivary statherin is a particularly well studied acidic phosphoprotein that inhibits the nucleation and growth of calcium phosphate minerals in the oral environment, and acts as a boundary lubricant.^{82–87} The N-terminus of statherin is highly charged, with the first five amino acids containing one aspartic acid, two phosphorylated serines, and two glutamic acids that have been shown to be important in the recognition of HAP⁸³ (Figure 6). A solution NMR study of statherin,⁸⁷ acquired in a water/TFE solvent mixture, found the N-terminus to be alpha helical and the C-terminus was judged to be a 3₁₀ helix, although the relative paucity of NOE's in the C-terminus was interpreted as indicating non-rigidity. Recent solid state NMR studies have shown that the N-terminal 15 amino acid peptide derived from statherin (called SN-15), which is believed to constitute the bulk of the HAP binding site, is partly helical on the HAP surface.⁸⁸ Also, while the N-terminal 3–6 amino acids are immobilized on the surface, the remaining portion of the peptide toward the C-terminus show increased mobility.⁸⁹

However, to conclusively define the structure of the HAP-binding domain, the full-length protein must be studied on the mineral surface. In this section, we show how solid state NMR techniques have been applied to full length phosphorylated statherin on the hydroxyapatite crystal surface to characterize the high-resolution structure and dynamics of the N-terminal binding domain under hydrated and lyophilized conditions.

Site-specific isotopic labeling of statherin allowed structural determinations to be made unambiguously using the dipolar recoupling techniques DQDRAWS^{90,91} and REDOR. DQDRAWS, a double-quantum variant of the DRAWS homonuclear recoupling technique, was applied to measure the distance between adjacent backbone carbonyl carbons and thus yield model-free determination of the backbone torsion angle φ . Determination of individual torsion angles yields insights into local secondary structure as well as structural heterogeneity. Typically α -helices are indicated by torsion angle values in the range of -45° to -80° with a mean of -63° (Figure 7). The average values of β -sheets are somewhat larger, varying from -80° to -150° with a mean of

Figure 6 The primary sequence of the 43 amino acid protein salivary statherin and a possible structure based on solution and solid state NMR data

Figure 7 The carbonyl-carbonyl distance in the backbone of a polypeptide for various secondary structure motifs

−130°. REDOR, a heteronuclear recoupling technique, was used to measure the distance between the backbone carbonyl carbon and the backbone nitrogen involved in the hydrogen bond of a putative α -helical domain. This measurement is very sensitive to global secondary structure since theoretical distances expected for classical secondary structures vary from 4.2 Å for an α -helix to 10.6 Å for a β -sheet. Although isotropic chemical shifts of proteins can give qualitative indications of secondary structure in homogeneous systems, their values can be influenced by the bulk magnetic susceptibility of the support in heterogeneous systems. This makes them unreliable for structural determination in proteins closely associated with or adsorbed on inorganic surfaces such as HAP. Solid state NMR of ^{13}C nuclei is also very sensitive to dynamics, which can be probed over several orders of magnitude by measuring chemical shift anisotropies (CSAs), relaxation constants including carbon T_1 's and $T_{1\rho}$'s, and proton $T_{1\rho}$'s.

The structure and dynamics of salivary statherin were analyzed at the pS₂, pS₃, F₇, L₈, I₁₁ and G₁₂ residues. Pairs of backbone carbonyl carbons were enriched at the pS₂pS₃, F₇L₈, and I₁₁G₁₂ positions in separate samples and probed using DRAWS and DQDRAWS. A ^{13}C enriched carbonyl carbon was introduced at the (i) position with an ^{15}N enriched amide nitrogen at the (i + 4) position in pS₃F₇ and L₈G₁₂ samples and probed using REDOR to verify the presence or absence of hydrogen bonding. The dipolar recoupling data for the pS₂pS₃ and pS₃F₇ samples are shown in Figure 8. All 5 samples were characterized using standard ^{13}C CPMAS and $T_{1\rho}$ relaxation sequences to measure any averaging of carbonyl carbon CSAs, cross polarization efficiencies, or relaxation due to the presence of motion. Measurements on all samples were performed under in situ conditions (i.e. buffered and hydrated) as well as after lyophilization. These results are summarized in Table 1.

Both the single torsion angle measurements and the distances between putative hydrogen bond donors and acceptors indicate the N-terminal 12 residues in statherin are in an α -helical conformation when adsorbed to HAP under biologically relevant conditions. Removal of water via lyophilization under low vacuum (i.e. 100 mTorr) results in loss of this structure in the highly acidic N-terminal 6 residues. The extension of the helix during lyophilization suggests a significant role for water in stabilizing the binding domain. Water may mediate the interaction of the acidic sidechains with the HAP surface. The α -helix has been previously suggested as a general structural mechanism for aligning acidic side-chain residues with HAP,⁹² either through lattice matching or through more general electrostatic complementarity. While our data support the presence of this secondary structure, they also point to the possible importance of water in HAP binding.

The dynamic properties of the immobilized protein are a critical aspect of molecular recognition at the

Figure 8 (a) REDOR dephasing curves for hydrated, surface adsorbed pS₃F₇ Statherin (◆), lyophilized, bound pS₃F₇ statherin (◇), and simulations for 4.2 Å (unbroken blue line), 5.2 Å (dashed red line) and a combination of 45% α -helix (4.2 Å) and 65% β -sheet (>8 Å) (unbroken red line). The hydrated pS₃F₇ distance across the hydrogen bond fits best to a distance of 4.3 Å, indicating that the region is well described by an ideal α -helix. Data for the lyophilized sample is best simulated by 5.2 Å or a combination of 35% α -helix and 65% β -sheet, indicating a loss in α -helical secondary structure upon lyophilization. (b) DQDRAWS buildup curves for hydrated, surface adsorbed pS₂pS₃ statherin (◆), lyophilized, bound pS₂pS₃ Statherin (◇), and simulations for ϕ torsion angles of −60° (unbroken blue line), −85° (dashed red line) and a combination of 45% α -helix (−57°) and 65% β -sheet (−120°) (unbroken red line). The increase in torsion angle on lyophilization correlates well with the loss of α -helical secondary structure

Table 1 Values for the anisotropy ($\Delta\sigma$) and asymmetry (η) of the CSA, average values of the torsion angle (φ), distance measurements across putative hydrogen bonds and ^{13}C $T_{1\rho}$ relaxation constants measured for indicated residues of salivary statherin bound to HAP in the presence and absence of water

Isotopic label	$\Delta\sigma$ (ppm)		η		φ /distance		$T_{1\rho}$ (ms)	
	Lyo.	Hyd.	Lyo.	Hyd.	Lyo.	Hyd.	Lyo.	Hyd.
pS ₂	114	105	0.96	0.74			>20	18.2
pS ₃	109	104	0.81	0.79	−85°(11)	−60°(10)		
pS ₃ F ₇					5.2(0.6) Å	4.3(0.2) Å		
F ₇	103	99	0.73	0.61			>20	7.5
L ₈	103	98	0.72	0.69	−77°(20)			
L ₈ G ₁₂					4.8(0.4) Å	4.8(0.4) Å

protein-biomaterial interface, and relatedly to the function of proteins once adsorbed. Measurements of the dynamic properties of statherin in the presence and absence of water show a striking difference from the structural data. The ^{13}C $T_{1\rho}$ values remain largely unchanged for the phosphoserines, indicating little or no motion is present in both the lyophilized and hydrated states. However, the $T_{1\rho}$ relaxation constants are considerably shorter in the hydrated samples at the F₇, L₈, I₁₁ and G₁₂ positions, indicating motion on the kHz timescale when water is present. Figure 9 shows CPMAS spectra for each of the doubly carbon-labeled statherin

Figure 9 CPMAS spectra of (a) pS₂pS₃ Statherin bound to the surface and lyophilized, (b) hydrated, surface-adsorbed pS₂pS₃ Statherin (c) hydrated, surface-adsorbed F₇L₈ Statherin and (d) hydrated, surface-adsorbed I₁₁G₁₂ Statherin. Each hydrated spectrum is normalized to the natural abundance methyl region. The significant decrease in the carbonyl signal for the F₇L₈ and I₁₁G₁₂ hydrated spectra is indicative of molecular motion. $T_{1\rho}$ relaxation measurements support the interpretation of minimal mobility at the pS₂pS₃ region and increased mobility for the F₇L₈ and I₁₁G₁₂ regions

samples under hydrated conditions, normalized to the natural abundance methyl region to account for any differences in the amounts of bound protein. A representative spectrum of a lyophilized, surface bound sample labeled at the pS₂ and pS₃ positions is also shown for comparison. The significant loss in CP efficiency at the F₇, L₈, I₁₁ and G₁₂ positions in the hydrated samples is also characteristic of mobility. These measurements bracket the timescale of the motion in this region to 10^{-3} – 10^{-5} s. In contrast, the hydrated, surface bound pS₂pS₃ region does not display a loss in CP efficiency, indicating there is very little motion in that region on the timescale of the cross polarization experiment. The CSAs were found to narrow very little, with spans ($\Omega = |\sigma_{11} - \sigma_{33}|$) of approximately 140–150 ppm in the hydrated samples, as compared to 145–155 ppm for their lyophilized counterparts. The small change in the CSA under hydrated conditions indicates that the motion observed in the cross polarization experiments and supported by the $T_{1\rho}$ relaxation measurements somewhat restricted. Motion was observed in analogous regions for the isolated SN15 peptide, but significant narrowing of the CSA was observed at the C-terminal residues of the peptide (I₁₁ and G₁₂). The nearly unchanging CSA observed for the entire N-terminus of statherin indicates a different motional mode present in the full protein. The $T_{1\rho}$ relaxation parameters for both protein and peptide are nearly the same, which would support a motion of similar frequency, but different amplitude than that observed in the SN15 peptide. The change in mobility could be due to one of several factors, including motional limitations due to the larger size of the protein, stabilization of the peptide backbone by tertiary structure, or potentially due to more substantial protein interactions with the surface at the C-terminal end of full statherin.

To explore the latter possibility, the only negatively charged residue outside of the N-terminus was replaced with its uncharged counterpart (Glu₂₆ → Gln₂₆). This site-directed statherin mutant displayed a $T_{1\rho}$ value at I₁₁G₁₂ of 2.9 msec, identical to the $T_{1\rho}$ value at the same positions of the unmodified protein (2.5 ms) within experimental uncertainty. This indicates that Glu₂₆ is not involved in HAP recognition to an extent that prevents kHz frequency motions in the N-terminal region. The simplest explanation of the results is that either the larger size of full-length statherin or tertiary structural interaction is causing the lower amplitude dynamics compared to the isolated SN15 peptide, rather than being due to a different type of interaction with the HAP surface. However, the dynamics data could also be explained by more complicated models that do include protein interactions

Figure 10 Schematic model showing statherin interacting with the 001 face of HAP, with calcium ions in white and phosphoserines in purple. The protein colors represent backbone ^{13}C = O-enriched (red), ^{15}N -enriched (blue), and unenriched (yellow) residues. The REDOR-measured hydrogen bonding distances are indicated for the hydrated N-terminal binding domain, while the remaining portion of the protein (blue) is shown as a nondescript shape to indicate unknown surface adsorbed structure (hydrogen bonds in white). The strong interaction of the N-terminus through the immobile phosphoserines is indicated, and the more mobile, non-interacting C-terminus of the pentadecyl domain is shown oriented away from the HAP surface

with the surface outside of the N-terminal domain. It is clear, however, that both the protein and peptide are only loosely associating with HAP outside of the anionic N-terminal pentapeptide region. The pentapeptide sequence is a common motif in many bone and tooth-associated proteins. It is also a recognition sequence for phosphorylation. The importance of the phosphorylated serines in statherin in binding to HAP indicates a possible regulatory mechanism for multifunctional proteins, such as osteopontin, which are found to be important in regulating mineralization in some settings, but are found in other tissues as well.

A molecular model consistent with the current structural and dynamic studies is shown in Figure 10. The N-terminal domain from residues 2 to 12 is helical on the surface. The strong interaction of statherin with HAP is mediated by the acidic N-terminus, where two phosphoserines and three carboxylate-containing side-chains are located. The dynamics studies suggest that the remainder of the helix is much more weakly interacting with HAP. The more weakly interacting residues in this domain could be viewed as a flexible rod, with torsional motions increasing with increasing distance from the highly immobile N-terminal pentapeptide sequence. The presence of a highly mobile protein segment could explain functional observations made previously by others in the field. Moreno et al.⁹³ found that statherin inhibited secondary crystal growth at a higher level than that expected based on coverage size, assuming a fixed, globular protein. The mobility of statherin could allow it to effectively block more nucleation sites than a completely rigid protein. The mobility of statherin on the surface may also play a significant role in the lubricating properties of the protein. To adequately model the observed motions at the molecular level, further details of the surface bound tertiary structure and experimental elucidation of the side-chain interactions with HAP will be required to orient statherin at the surface. Solid-state NMR does provide a direct

route to this information, and we are currently probing the tertiary structure and the interactions of side chains with the surface to further elucidate binding mechanisms.

1 INTRODUCTION

In principle, accurate interatomic distances can be evaluated from careful analysis of specific dipolar interactions that were normally sacrificed under the condition of high power decoupling and magic angle spinning (MAS) techniques. A number of methods to recouple a single pair of dipolar interaction among homo and hetero nuclear spin pairs under the magic angle spinning condition have been proposed for determining the interatomic distances.^{1–10} These distances have been used as constraints to determine the three-dimensional (3D) structure of peptides and proteins.^{11–16} Rotational Echo DOuble Resonance (REDOR) was explored to recouple the relatively weak heteronuclear dipolar interactions under the MAS condition by applying a π pulse synchronously with the rotor period.^{8,9} Consequently, the transverse magnetization cannot be refocused completely at the end of the rotor cycle, leading to a reduction of the echo amplitude. The extent of the reduction of the echo amplitude as a function of the number of rotor periods depends on the strength of the heteronuclear dipolar interaction. This method is extensively used to determine the relatively remote interatomic distance of 2–8 Å. When a number of isolated pairs are involved in a REDOR dephasing,

the REDOR transformation could be useful in determining interatomic distances because it yields single peaks against distance axis for each heteronuclear coupling strength.^{17,18} This approach is, however, not applicable for the case where the observed nuclei in REDOR are coupled with multiple nuclei.

It turned out that determination of accurate interatomic distances (± 0.1 Å) is a prerequisite to arrive at a unique 3D structure of peptides and proteins.^{15,16} It is emphasized that the distance measurement by REDOR is the only available means to satisfy this condition among the many kinds of proposed procedures mentioned above in view of the achieved accuracy and precision. Nevertheless, it is important to bear in mind that every possible effort to achieve the distance measurement with ultimate accuracy is essential to any possible applications. This is because any measurement based on the peak-intensity is susceptible to unexpected errors, which are not easy to check. After brief survey, tips to avoid this problem will be discussed in detail.

2 THEORETICAL BACKGROUND OF THE REDOR EXPERIMENT⁸

Transverse magnetization that precesses about the static magnetic field due to the dipolar interaction under the MAS condition moves back to the same direction at every rotor period because the integration of ω_D over one rotor period is zero. Consequently, the rotational echo signals are refocused at every rotor period. When a π pulse is applied to the I nucleus (Figure 1), which is coupled with the S nucleus, in one rotor period, this pulse plays a role to invert the precession direction of the magnetization of the observed S nucleus. Consequently, the magnetization vector of the S nucleus cannot move back to the same direction after one rotor period. Therefore the amplitude of the echo intensity decreases.

The extent of the reduction of the rotational echo amplitude yields the interatomic distances. To evaluate the REDOR echo amplitude theoretically, one has to consider the average precession frequency in the presence of the π pulse at the center of the rotor period over one rotor cycle as follows:

$$\begin{aligned} \overline{\omega_D(\alpha, \beta)} &= \pm \frac{1}{\text{Tr}} \left[\int_0^{\text{Tr}/2} \omega_D dt - \int_{\text{Tr}/2}^{\text{Tr}} \omega_D dt \right] \\ &= \pm \frac{D}{\pi} \sqrt{2} \sin 2\beta \sin \alpha \end{aligned} \quad (1)$$

Figure 1 Pulse sequence and timing chart of REDOR experiment

2 NUCLEAR INTERACTIONS

where α is the azimuthal angle and β is the polar angle defined by the internuclear vector with respect to the rotor axis. Therefore, the phase angle, $\Delta\Phi(\alpha, \beta)$ for the Nc rotor cycle can be given by

$$\Delta\Phi(\alpha, \beta) = \overline{\omega_D(\alpha, \beta)} NcTr \quad (2)$$

where Tr is the rotor period. Finally, the echo amplitude can be obtained by averaging over every orientations as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \cos[\Delta\Phi(\alpha, \beta)] d\alpha \sin\beta d\beta \quad (3)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by

$$\frac{\Delta S}{S_0} = \frac{S_0 - S_f}{S_0} = 1 - S_f \quad (4)$$

Experimentally, REDOR and full echo spectra are acquired for a variety of NcTr values and the respective REDOR (S_f) and full echo (S_0) amplitudes are evaluated.

3 ROTATIONAL ECHO AMPLITUDE CALCULATED BY THE DENSITY OPERATOR APPROACH¹⁵

The REDOR echo amplitude can be evaluated more rigorously by using density matrix operators and for the REDOR experiment. The time evolution of density operator, ρ_0 , under the heteronuclear dipolar interaction during one rotor period, can be considered by taking the pulse length into account. The average Hamiltonian in the rotating frame over one rotor period can be given by

$$\begin{aligned} \overline{\mathcal{H}} &= \frac{1}{Tr} \left[\overline{\mathcal{H}_1(t)\tau} + \overline{\mathcal{H}_2(t)\tau} + \overline{\mathcal{H}_3(t)\tau} \right] \\ &= \frac{D}{4\pi} \left\{ \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w) - 2\sin 2\alpha] \right. \\ &\quad - 2\sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) + 2\sin 2\alpha \right] \\ &\quad - \sin^2\beta [\sin(2\alpha + \omega_r t_w) + \sin(2\alpha - \omega_r t_w)] \frac{4\omega_r^2 t_w^2}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad + \sqrt{2}\sin 2\beta \left[\sin\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \sin\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\omega_r^2 t_w^2}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Z \\ &+ \frac{D}{4\pi} \left\{ \sin^2\beta [\cos(2\alpha + \omega_r t_w) + \cos(2\alpha - \omega_r t_w)] \right. \\ &\quad \times \frac{2\pi\omega_r t_w}{4\omega_r^2 t_w^2 - \pi^2} \\ &\quad - \sqrt{2}\sin 2\beta \left[\cos\left(\alpha + \frac{1}{2}\omega_r t_w\right) + \cos\left(\alpha - \frac{1}{2}\omega_r t_w\right) \right] \\ &\quad \times \frac{2\pi\omega_r t_w}{\omega_r^2 t_w^2 - \pi^2} \left. \right\} \hat{I}_Z \hat{S}_Y \\ &= a\hat{I}_Z \hat{S}_Z + b\hat{I}_Z \hat{S}_Y \end{aligned} \quad (5)$$

where ω_r is the angular velocity of the rotor and t_w is the duration of π pulse. $\overline{\mathcal{H}_1(t)}$, $\overline{\mathcal{H}_2(t)}$, and $\overline{\mathcal{H}_3(t)}$ are the average Hamiltonians corresponding to the period shown in Figure 1. Pulse length, t_w , is also considered in the calculations for the analysis of the REDOR results. The density operator, ρ (Tr), at Tr after evolution under the average Hamiltonian can be calculated as

$$\rho(Tr) = \exp(-i\overline{\mathcal{H}}Tr)\rho_0\exp(i\overline{\mathcal{H}}Tr) \quad (6)$$

where ρ_0 is considered to be $\hat{I}_Y$ after the contact pulse. Then finally the transverse magnetization at Tr can be given by

$$\begin{aligned} \langle \hat{I}_Y(Tr) \rangle &= Tr\{\rho(Tr)\hat{I}_Y\} \\ &= \cos\left(\frac{1}{2}\sqrt{a^2 + b^2}Tr\right) \end{aligned} \quad (7)$$

Echo amplitude in the powder sample can be calculated by averaging over every orientation as follows

$$S_f = \frac{1}{4\pi} \int_{\alpha} \int_{\beta} \langle \hat{I}_Y(Tr) \rangle \sin\beta d\beta d\alpha \quad (8)$$

Therefore, the normalized echo difference, $\Delta S/S_0$, can be given by equation (4). When the length of t_w is zero, equation (7) can be simplified as follows:

$$\langle \hat{I}_Y(Tr) \rangle = \cos\left(\frac{D}{\pi}\sqrt{2}\sin 2\beta \sin \alpha Tr\right) \quad (9)$$

In this case, equation (8) is equivalent to equation (3) in the case of Nc = 1.

4 SEPARATION OF S-I DISTANCES FROM A S_m-I_n MULTIPLE SPIN SYSTEM

It should be taken into account that a spin system for a doubly labeled sample should be generally treated as a multiple spin system ($S-I_n$ system) as shown in Figure 2(a) in which S^* is the observed nuclei and the recoupling pulse is applied to the I^* nuclei. The ideal S-I system is available only when the doubly labeled preparation is infinitely diluted with unlabeled preparation. In contrast, uniformly and singly labeled preparations are treated as S_m-I_n and $S-I_n$ systems, respectively (Figure 2b,c), although S^* in the latter is S nuclei of natural abundance. For this reason, it is advisable to utilize a variety of isotopically doubly labeled samples in order to obtain respective interatomic distances, although it is too laborious to make so many kinds of preparations. In fact, we made six kinds of doubly labeled preparations to determine the 3D structure of the pentapeptide, Leu-enkephalin.¹⁶ In addition, it is essential to make certain that all such preparations take the same polymorphic structure, because crystalline peptides or proteins under consideration may take different kinds of polymorphs depending on condition for crystallization, pH, temperature, etc.^{15,16} The most convenient way to check this problem is to use the conformation-dependent ¹³C chemical shifts,

Figure 2 Schematic representation of multiple spin systems for (a) doubly labeled, (b) uniformly labeled and (c) singly labeled samples

which are very sensitive to the presence of such polymorphic structure.^{15,16,19}

In this connection, use of a uniformly labeled sample seems to be more attractive both for the sample preparation and also to avoid the problem of polymorphs.²⁰ This view turned out to be not always true, however, because separation of a particular $S-I$ interaction from S_m-I_n spin systems, consisting of many homo- and heteronuclear dipolar and scalar interactions, is not always as straightforward as anticipated. In practice, all of the following conditions should be taken into account to determine the accurate interatomic distances of a particular spin pair from the uniformly labeled samples. First, J coupling among the observed S nuclei should be removed to reduce the phase twist due to the coherent evolution by J coupling, when its magnitude is comparable to the dipolar coupling, as illustrated for uniformly [^{15}N , ^{13}C]-labeled ammonium L-glutamate monohydrate at $\text{NcTr} = 8$ ms (Figure 3).^{21,28} This phase twist can be removed by using a shaped pulse as a Z-filter instead of a π pulse at the center position of the REDOR evolution period.²¹ Second, the linewidths of individual signals might be broadened due to strong homonuclear dipolar interaction with neighboring S nuclei, which should be eliminated by homonuclear decoupling pulses.²² Thus, in the case of a uniformly labeled sample, combination of both homonuclear dipolar and scalar decoupling is required to simplify the S_m-I_n to $S-I_n$ spin system. Third, relatively shortened transverse relaxation times (T_2), due to residual dipolar interactions, reduce the

Figure 3 ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8$ ms for crystalline uniformly labeled ammonium [^{15}N]-L-glutamate monohydrate

transverse magnetization during the dipolar recoupling period in REDOR experiments. This makes it difficult to observe the REDOR effect for the nuclei with relatively long internuclear distances, because it is required to measure relatively long evolution times to observe slow dephasing of the REDOR signals. Fourth, REDOR factors against the dipolar evolution time should be analyzed using multiply coupled $S-I_n$ spin systems rather than an isolated two-spin system under the condition of homonuclear decoupling.^{23–26} Accordingly, the four kinds of obstacles mentioned above should be removed to determine a set of accurate interatomic distances simultaneously for a uniformly labeled sample.

Gullion et al.²⁷ proposed a θ -REDOR as an approach to determine the individual interatomic distance in a uniformly labeled sample by dividing $S-I_n$ spin system into ' n ' number of isolated $S-I$ two-spin systems. This makes the REDOR analysis simple and allows one to use the REDOR transformation to obtain the dipolar coupling frequencies of individual $S-I$ spin couplings, although this method is not always easy to apply for measurement of a relatively long interatomic distance. Alternatively, homonuclear and scalar interactions are completely removed when natural abundant ^{13}C REDOR experiments were performed.²⁸ This approach provides an excellent means to determine the interatomic distances for a number of isolated spin pairs simultaneously under condition of high resolution (Figure 2c). Further, it is emphasized that this approach is free from the problem of the above-mentioned shortened T_2 values due to homonuclear ^{13}C spin interactions. However, a multiple coupled spin system, $^{13}\text{C}-^{15}\text{N}_n$, has still to be explicitly considered, because the intermolecular dipolar interactions cannot be neglected for a small molecule. In practice, we have recently demonstrated that accurate interatomic distances can be determined by analyzing intramolecular and

intermolecular dipolar contributions based on root mean square deviation (RMSD) between the theoretically and experimentally obtained REDOR factors.²⁸

5 TIPS FOR OBTAINING ACCURATE INTERATOMIC DISTANCES BY REDOR EXPERIMENT

It is emphasized that determination of interatomic distances accurate to 0.1 Å is a prerequisite to arrive at a unique solution of the three-dimensional structure of peptides, proteins, etc. A careful evaluation of the following points are the most important steps to obtain reliable interatomic distances by the REDOR experiment, although they have not always been seriously taken into account in a number of papers so far published.

5.1 The Finite Pulse Length and Fluctuation of RF Power

This effect is experimentally observed and calculated using equation (8) as shown in Figure 4. The REDOR parameter, $\Delta S/S_0$, as measured for 20% [1-¹³C, ¹⁵N]Gly($r_{\text{CN}} = 2.48$ Å) is plotted for the lengths of the ¹⁵N π pulse of 13.0 μs for the experiment and 24.6 μs (chosen to satisfy 10% rotor cycle) as a function of NcTr with the calculated lines using the π pulse

Figure 4 ¹³C REDOR and full echo spectra of [1-¹³C, ¹⁵N]glycine as recorded by the rotor frequency of 4000 Hz and NcTr of 4 ms (a) and plots of the $\Delta S/S_0$ vs. NcTr (b). Solid and open circles denote the experimental points recorded using a ¹⁵N π -pulse of 13.0 and 24.6 μs , respectively. Solid, broken and dotted lines are calculated using the π -pulses of δ , 13.0 and 24.6 μs , respectively, together with the C–N interatomic distance of 2.48 Å¹⁵

length and finite lengths (13.0 and 24.6 μs) of the π pulse. It turns out, however, that the finite length of the ¹⁵N π pulse does not significantly affect the REDOR effect provided that the pulse length is less than 10% of the rotor cycle at the rotor frequency of 4000 Hz. This effect, however, should be seriously taken into account if fast MAS, e.g., 40 kHz is used.

For most spectrometers, it is difficult to be free from fluctuations of RF power during the acquisition of REDOR experiments. It is, therefore, critical that RF power be stabilized. If not, the π pulse will vary in length. Consequently, the REDOR factor is greatly decreased to yield relatively longer interatomic distances. Compensation of instability of such RF power, e.g., by approximate pulse sequence is, therefore, necessary to be free from long term fluctuations of amplifiers. xy-4 and xy-8 pulse sequences have been developed for this purpose. The xy-8 pulse is known to be the best sequence to compensate for the fluctuation of the RF power.²⁹

5.2 Contribution from Natural Abundance Nuclei

Since the early stages of the REDOR experiment, contributions from natural abundance nuclei have been seriously considered as a major source of error in the distance measurement.³⁰ It appears that the observed dipolar interaction can be modified by the presence of such neighboring naturally abundant nuclei. This effect was originally taken into account by simply calculating the $\Delta S/S_0$ value for two isolated pairs and adding proportionally to the natural abundant fraction.³⁰ Careful analysis of the three-spin system, however, indicates that this sort of simple addition of the fraction of the two-spin system may result in a serious overestimate of the natural abundance effect, to yield shorter distances.²³ The most accurate way to consider the natural abundance effect is, therefore, to treat the whole spin system as a three-spin system by taking into account the neighboring carbons in addition to the labeled pair. In practice, contributions from naturally abundant nuclei can be ignored for ¹³C REDOR but not for ¹⁵N REDOR, because the proportion of naturally abundant ¹³C nuclei is much higher than that of the ¹⁵N nuclei.²³

5.3 Sample Dilution

¹³C, ¹⁵N-doubly labeled samples are usually used in the REDOR experiment to determine the interatomic distances between the labeled nuclei. More importantly, the dipolar interaction with the labeled ¹⁵N nuclei for the neighboring molecules should be taken into account as an additional factor to contribute to the dipolar interaction of the observed pair under consideration. This contribution could be serious when the observed distance is quite remote, because there are many contributions from nearby nuclei. This effect can be completely removed by diluting the labeled sample with a sample of naturally abundant molecules.²³ The sensitivity of the signals, however, has to be sacrificed if one wants to remove the effect completely as the sample must be diluted to 1/49 so that the signal intensity is reduced by a factor roughly 0.02.¹¹ Instead, it is advised to evaluate the REDOR factors at the infinitely diluted condition by extrapolating the data by stepwise dilution of the sample (i.e., 60%, 30%, etc.) without losing sensitivity, because a linear relationship between the REDOR factor and the dilution is ascertained by a theoretical consideration.²³ Alternatively, the observed plots of $\Delta S/S_0$ values against the

corresponding NcTr values for the sample without dilution can be fitted by a theoretical curve obtained from the dipolar interactions among three-spin systems, although the accuracy is not always improved to the level of the dilution experiment.

5.4 T_2 Effect

The transverse magnetization of the REDOR experiment decays as a function of the ^1H decoupling field.^{31,32} Under appropriate conditions, molecular motion may interfere with dipolar decoupling. This occurs when molecular motion, if any, exists when the motional frequency is of the same order of magnitude as the decoupling field, and hence the transverse relaxation times (T_2) are significantly shortened. In fact, it was found that the T_2 values of the carbonyl carbons in crystalline Leu-enkephalin are relatively short because of the presence of backbone motion.³³ This is a serious problem for the REDOR experiment, especially for the long distance pairs, because the S/N ratio is significantly deteriorated. In this case, it is required to measure the ^{13}C REDOR signal under a sufficiently strong decoupling field to elongate the transverse relaxation times. It is also useful to perform measurements at low temperature so as to reduce the motional frequency. Note, however, that crystalline phase transitions might be associated together with the freezing of the solvent molecules. This effect has been observed in a variety of enkephalin samples.^{34,35}

5.5 RF Inhomogeneity and Confinement of the Sample within RF Coil

In the commercial spectrometer, the rotor is designed to allow the sample volume to be as large as possible in order to gain better sensitivity. Obviously, this arrangement causes H_1 inhomogeneity, which results in a broad distribution of the lengths of the 90° pulses. This problem is serious for the REDOR experiment in which a number of π pulses are applied. As a result, the pulse error can accumulate during the acquisition to give serious error in the measurements of internuclear distances. Particularly, the samples located at the top or bottom part of the sample rotor feel quite a weak RF field. This causes a great reduction of the REDOR factor for a sample that is filled all the way along the sample rotor.¹⁵ This effect should be seriously taken into account prior to experiments with a commercial spectrometer. It is, therefore, strongly recommended to fill the sample only in the central part of the coil just like a multiple pulse experiment to be able to acquire as accurate interatomic distances as possible in the REDOR experiment.

5.6 Standard Sample

All of the considerations mentioned above are essential to achieve accurate interatomic distances. Nevertheless, it is also possible that accuracy may deteriorate even if one of the conditions is not satisfied for every possible measurement. It is therefore advisable to determine the interatomic distances from a standard sample, in order to check that all the conditions are satisfied. More preferentially, use of two standard samples for short and long distances is recommended. In practice, it is recommended to use [$1\text{-}^{13}\text{C}$, ^{15}N]glycine as the former standard sample whose C–N interatomic distance is determined as 2.48 Å by a neutron diffraction study, and to check that all the instrumental conditions of a given spectrometer are satisfied prior to every new experiment. As a second standard sample for long distance, it is recommended to use [^{13}C , ^{15}N]N-acetyl-Pro-Gly-Phe (Table 1). This crystalline peptide is very stable with relatively long T_2 values, because it does not contain solvent molecules, and the presence of two polymorphic structures is well characterized.¹⁵

6 NATURAL ABUNDANCE ^{13}C REDOR EXPERIMENT²⁸

As mentioned already, it is impossible to obtain meaningful interatomic distances from a uniformly labeled sample as far as the standard REDOR procedure is concerned. Instead, the natural abundance REDOR experiment is more preferable as a means free from both homonuclear dipolar and scalar interactions (Figure 3). This approach provides the interatomic distances for a number of isolated spin pairs simultaneously under high resolution conditions. Further, this approach is free from the problem of the shortened T_2 values due to homonuclear ^{13}C spin interactions. Figure 5 shows the REDOR and full echo spectra of natural abundance ^{13}C nuclei of singly ^{15}N labeled crystalline ammonium [^{15}N]L-glutamate monohydrate (I) at NcTr = 8 ms, in contrast to the twisted spectra from the same sample uniformly labeled (Figure 3). The assignment of peaks to the C_β , C_γ , C_α , $\text{C}=\text{O}$ and C_δ carbon nuclei, from high to low field, is also shown in Figure 5. The $\text{C}=\text{O}$ (176.6 ppm) peak was distinguished from the C_δ (179.5 ppm) peak as a peak yielding a stronger REDOR effect as shown in Figure 5. Similarly, the peak at 56.0 ppm was assigned to the C_α carbon nucleus that give the strongest REDOR effect among the three aliphatic ^{13}C peaks. In a similar manner, the peak at 30.5 ppm showed a stronger REDOR effect compared

Table 1 C–N interatomic distances (Å) determined from REDOR experiments as compared with those by X-ray diffraction and MD¹⁵

Labeled peptides	Experimental			Calculated		
	REDOR	X-Ray		Energy-minimized ^a	MD	
	Orthorhombic	Orthorhombic	Monoclinic ^b		Orthorhombic	Monoclinic
I	3.24 ± 0.05 (3.43 ± 0.05) ^c	3.19	3.76	3.17	3.22 ± 0.10	3.63 ± 0.10
II	3.43 ± 0.05 (3.66 ± 0.05)	3.35	3.21	3.57	3.32 ± 0.10	3.33 ± 0.10

Figure 5 Naturally abundant ^{13}C -REDOR and full echo spectra at $\text{NcTr} = 8\text{ ms}$ with two different carrier frequencies for crystalline ammonium ^{15}N -L-glutamate monohydrate. Arrows indicate carrier frequency positions at the center of (a) $\text{C}=\text{O}$ and C_δ resonances; and (b) C_β and C_γ resonances

with that at 35.2 ppm. Thus, the peaks at 35.2 and 30.5 ppm were assigned to the C_γ and C_β carbon nuclei, respectively.

The interatomic C–N distances between ^{15}N and $^{13}\text{C}=\text{O}$, $^{13}\text{C}_\alpha$, $^{13}\text{C}_\beta$, $^{13}\text{C}_\gamma$, and $^{13}\text{C}_\delta$ carbon nuclei were determined with accuracy of 0.15 Å, after experimental conditions were carefully optimized. ^{13}C -REDOR factors for a three-spin system, $(\Delta S/S_0)_{\text{CNIN}_2}$, and the sum of two isolated two-spin systems, $(\Delta S/S_0)^* = (\Delta S/S_0)_{\text{CN}_1} + (\Delta S/S_0)_{\text{CN}_2}$, were further evaluated by the REDOR measurements on isotopically diluted I in a controlled manner. Subsequently, the intramolecular and intermolecular C–N distances were separated by searching the minimum in the contour map of the root mean square deviation (RMSD) between the theoretically and experimentally obtained $(\Delta S/S_0)^*$ values against two interatomic distances, $r_{\text{C}-\text{N}_1}$ and $r_{\text{C}-\text{N}_2}$. When the intramolecular C–N distance ($r_{\text{C}-\text{N}_1}$) of the particular carbon nucleus is substantially shorter than the intermolecular distance ($r_{\text{C}-\text{N}_2}$), C–N distances between the molecule in question and the nearest neighboring molecules can also be obtained, although accuracy is inevitably deteriorated. On the other hand, it was difficult to determine the interatomic distances in the same molecule

when the intermolecular dipolar contribution is larger than the intramolecular one as in the case of the C_δ carbon nucleus.

7 ACCURACY LIMIT FOR REDOR STRUCTURE OF PEPTIDE AND PROTEINS

Naito et al.¹⁵ systematically applied this technique to elucidate the three-dimensional structure of *N*-acetyl-Pro-Gly-Phe. They proposed that the carbonyl carbon of the (*i*-1)th residue and the amino nitrogen of the (*i*+1)th residue should be labeled with ^{13}C and ^{15}N , respectively. Namely, $[1-^{13}\text{C}]\text{N}$ -acetyl-Pro- ^{15}N -Gly-Phe(I), *N*-acetyl- $[1-^{13}\text{C}]\text{Pro}$ -Gly- ^{15}N -Phe(II) and $[1-^{13}\text{C}]\text{N}$ -acetyl-Pro-Gly- ^{15}N -Phe(III) were synthesized and the resulting distances were determined to be 3.24 ± 0.05 , 3.43 ± 0.05 , and 4.07 ± 0.05 Å respectively, utilizing the REDOR factor obtained for the infinitely diluted state to prevent errors from the contributions of the neighboring labeled nuclei. No correction from the contribution of the naturally abundant nuclei turned out to be necessary. Surprisingly, these distances do not agree well with the values obtained from an X-ray diffraction study available when the initial part of this experiment was performed, showing the maximum discrepancy between them to be 0.5 Å.³⁶ This value seems to be much larger than the expected error as estimated from the precision of the REDOR experiment (± 0.05 Å). The reason why the discrepancy is unexpectedly larger was explained by the fact that the crystal (orthorhombic) used for the REDOR experiments is different from that used in the X-ray diffraction study (monoclinic). To check the accuracy of the REDOR experiment, an X-ray diffraction study was performed on the same crystals used for the REDOR experiment. It was found that the distances from the new crystalline polymorph (orthorhombic) agree well between REDOR and X-ray diffraction, within an accuracy of 0.05 Å as shown in Table 1.

Conformational maps based on the possible combinations of the torsion angles of the Pro and Gly residues are calculated on the basis of the distance constraints thus obtained. Further, the difference of the chemical shifts between the C_β and C_γ carbons of the Pro residues $\Delta\beta\gamma$ was used as a constraint to determine the ψ value (-13°).³⁷ The ϕ angle of the Pro residue is in many instances restricted to -75° which shows the minimum energy in the residue. Therefore, the torsion angles of the Pro residue are uniquely determined to be (-75° , -28°). Using these torsion angles, conformational maps were again calculated. Finally two pairs of torsion angles were selected as (-112° , 48°) and (-112° , -48°). Minimization by a molecular mechanics calculation yielded the structure of the β -turn I structure, as shown in Figure 6(a). It is found that the three-dimensional structure of this peptide is well reproduced by a molecular dynamics simulation by taking into account all of the intermolecular interactions in the crystals, although a molecular dynamics calculation treating *single* molecular system does not always yield a correct picture as illustrated in Figure 6(b), unless otherwise all the molecules in a unit cell are correctly taken into account.^{15,38}

Elucidation of the three dimensional structure of an opioid peptide Leu-enkephalin crystal, Tyr-Gly-Gly-Phe-Leu grown from MeOH/ H_2O mixed solvent was performed by the REDOR method alone.¹⁶ This seems to be an additional challenge for this technique to reveal the three-dimensional structure of more complicated systems. Six differently labeled

Figure 6 Optimized conformation of *N*-acetyl-Pro-Gly-Phe as obtained by the minimization of energy from the initial form as deduced from the REDOR experiment (a) and a snapshot of the conformation deduced by MD simulation in vacuo (at 100 K) (b)¹⁵

Leu-enkephaline molecules were synthesized and the resulting interatomic distances (Figure 7a) are accurately determined. It turns out, however, that an extremely careful experiment is required to avoid unexpected crystalline conversion among polymorphs either by dehydration from a tightly sealed rotor or a phase transition occurring at ambient temperature. In

principle, pressure under MAS may shift a temperature of phase transition to some extent, because centrifugal force is proportional to the square of the spinning frequency. No significant effect, however, has been noted so far as a sample is spun at relatively low frequency such as 2–4 kHz but care might be taken when rotor is spun at a frequency one order of magnitude high as in 40 kHz.

This may be the reason why final refinement of X-ray diffraction data was abandoned in spite of the pioneering X-ray diffraction data as to the similarity of the tertiary structure between this opioid peptide and morphine.³⁹ Therefore, it is necessary to check whether the six differently labeled samples are all in the same crystalline polymorph by means of the ¹³C chemical shifts. Otherwise, meaningless data can be obtained without this precaution. When the distance data are converted to yield the necessary numbers of torsion angles, a unique combination of torsion angles in the corresponding conformational map is determined sequentially as shown in Figure 7(b). It is emphasized that accuracy within 0.1 Å is essential to select unique torsion angles for each amino acid residue. Namely, if the error is larger than 0.41 Å, torsion angles can no longer be selected as shown in Figure 8.

It is also important to point out that the chemical shift data can be used as additional constraints. A three dimensional structure was thus determined as shown in Figure 9. However, this structure is not the same as that previously determined

Figure 7 (a) Schematic representation between the sites of a variety of [¹³C, ¹⁵N]-doubly-labeled Leu-enkephalin dehydrates and their related torsion angles. (b) Block diagram to show how respective torsion angles are uniquely determined by the combined examinations of the conformation maps based on the distances of four-bonds apart (I, II, III and VI) and five-bonds apart (IV and V)¹⁶

Figure 8 Conformation maps for $(\Psi_{\text{Gly2}}, \omega_{\text{Gly2}})$ based on the interatomic distance of 4.55 Å with increased experimental errors: (a) ± 0.10 Å, (b) ± 0.20 Å, and (c) ± 0.41 Å¹⁶

by X-ray diffraction because one is dealing with a crystalline polymorph that is not fully explored. It is possible to figure out the molecular packing in the crystals by looking at the intermolecular dipolar contribution. Since the intermolecular dipolar contributions in I and III are larger than that of II, a β -sheet is formed as one peptide interacts with two peptides as an antiparallel β -sheet as shown in Figure 9(b).

Finally, it should be pointed out that, in order to isolate an S–I spin pair, it is essential to avoid any unnecessary errors from dipolar contributions of neighboring molecules from the overall S–I_n spin system. This is generally encountered for a variety of peptides and the aforementioned dilution procedure turned out to be not required in the case of α -helical polypeptides as far as the measurement of the interatomic distance for $^{15}\text{NH}(i) \cdots \text{O} = ^{13}\text{C}(i+4)$ is concerned.⁴⁰ This is because the interhelical dipolar contribution is found to be negligible in view of the mutual packing of α -helical chains or random mutual orientation between isotopically labeled atoms. Further, it was found that in helical peptides, due to the manner of chain packing, this kind of measurement is feasible to yield 4.5 ± 0.1 Å, without any assumptions, for a variety of transmembrane α -helical peptides in lipid bilayers to mimic a biomembrane at a temperature below liquid crystalline-gel phase transition at which rotation of such peptides about the α -helical axis turns out to be frozen, in spite of the presence

Figure 9 (a) Three-dimensional structure of Leu-enkephalin dihydrate determined uniquely by the successive application of the conformation maps as well as additional constraints of the conformation-dependent ^{13}C chemical shifts. (b) Three kinds of models for putative intermolecular packing as illustrated in the cartoons: (1) interaction through parallel β -sheet form; (2) interaction through an antiparallel β -sheet; and (3) interaction through interaction of three molecules. Solid and dotted arrows correspond with the dipolar interactions between intramolecular ^{13}C – ^{15}N pairs, respectively¹⁶

of rotational motions of lipid molecules, as viewed from the observation of three principal components of ^{13}C and ^{31}P chemical shift tensors.⁴¹ As is shown in this example, it is essential to ensure that molecular motion is reasonably ceased.

8 CONCLUSIONS

REDOR is one of the most powerful methods to determine accurate interatomic distances after taking into account a number of points in applying the method to a practical sample. Simultaneous measurement of interatomic distances using uniformly labeled samples can only be achieved by removing the homonuclear dipolar and scalar interactions. Alternatively, natural abundance ^{13}C REDOR measurements provide interatomic distances simultaneously free from homonuclear dipolar and scalar interactions. These accurate interatomic distances obtained from REDOR experiments can provide important information on structure and molecular packing of solid peptides and proteins.

1 INTRODUCTION

Situated at the barrier between the interior and exterior of a cell or organelle, membrane proteins execute a variety of vital functions, including energy transduction (i.e. conversion of energy between different forms) and signal transduction (i.e. triggering a cascade of events in response to an environmental effector). The rhodopsins are light-transducing membrane proteins with a chromophore formed by a retinal molecule linked to the protein (known as the opsin) via a Schiff base with a lysine residue (Figure 1). Most rhodopsins are signal transducers: absorption of a photon induces a change in the rhodopsin that activates a primed system, leading to a visual response (e.g. in mammals) or phototactic response (e.g. in algae and archaeobacteria). However, two energy-transducing rhodopsins have been found in halophilic archaeobacteria: in these cases, absorption of a photon results in transport of an ion across the membrane, against its gradient, resulting in conversion of radiant energy into electrochemical energy which can be stored. One of these energy-transducing rhodopsins, known as bacteriorhodopsin because it was the first rhodopsin discovered in a unicellular organism, pumps protons and the other, known as halorhodopsin, pumps halide ions.

Bacteriorhodopsin (248 amino acids, 26 kDa) is the most thoroughly studied membrane protein. This is because it is a major product of *Halobacterium salinarium* (previously also known as *Halobacterium halobium*), and crystallizes in the plane of the membrane to form patches with 2D hexagonal order, from which all other proteins are excluded.¹ These

Figure 1 Protonated Schiff base of all-*trans*-retinal with a Lys side chain. X^- is the Schiff base counterion. The carbons atoms are identified according to convention by numbers on the retinal and Greek letters on the Lys residue

patches (known as ‘purple membranes’ due to the color of the pigment) are readily separated from the rest of the cell membrane and are stable and functional over an exceptionally wide range of conditions (including pH values, ionic strengths, and temperatures). Thus, it is relatively easy to prepare large samples of the protein in its native form. Due to the 2D crystalline order in the membranes, it has been possible to construct 3D electron density maps from electron micrographs taken over a range of tilt angles.² These studies show that the protein folds into a bundle of seven transmembrane helices that encapsulates the retinal chromophore. Chemical studies have shown that the retinal Schiff base is formed with Lys216.³ Neutron diffraction studies find that the retinal is located near the center of the membrane with the ionone ring closer to the extracellular side than the Schiff base.

Figure 2 shows the relationships between the functionally important forms of bacteriorhodopsin. In the dark, there is a thermal equilibrium between bR_{555} and bR_{568} , where the subscript indicates the wavelength of maximum visible absorbance. The photoproducts of bR_{555} (not shown) decay to bR_{568} , so that bR_{555} disappears upon light adaptation. The photocycle of bR_{568} is responsible for proton transport. The initial photoreaction is the isomerization of the chromophore from all-*trans* in bR_{568} to 13-*cis* in J_{625} . The proton on the Schiff base is lost in the L_{550} – M_{412} transition, and restored in the M_{412} – N_{520} transition. FTIR and kinetic studies, of wild-type and mutant samples, indicate that the immediate proton acceptor is Asp85, and the immediate proton donor is Asp96. However, the proton pathway traverses the entire membrane, and pumping occurs because a proton is released into the extracellular medium in the first half of the photocycle and taken up from the cytoplasm in the second half of the photocycle. The central question regarding the mechanism of bacteriorhodopsin is how this switch occurs: what prevents the system from being reprotonated from the extracellular side? For *Halobacterium*, bacteriorhodopsin

Figure 2 Relationships among the functionally important forms of bacteriorhodopsin. Subscripts indicate the wavelength of maximum visible absorbance. The chromophore is photoisomerized from all-*trans* to 13-*cis* in the bR_{568} to L_{550} photoreaction. The Schiff base is protonated in all but the M-states

provides a solar-powered alternative to respiration for creating the proton electrochemical potential gradient that is required for regeneration of ATP from ADP (the 'proton motive' force of the chemiosmotic mechanism).

Bovine rhodopsin (348 amino acids, 40 kDa) is the most thoroughly studied visual pigment, due to Western dietary habits. Rhodopsin is solubilized and purified from the rod cells of the retina, and then reconstituted into lipid bilayers. Although it does not naturally form a crystalline lattice, it can be induced to do so, and electron cryomicroscopy of such preparations indicates that rhodopsin also forms a bundle of seven transmembrane helices.⁴ The retinal Schiff base is formed with Lys296,⁵ and the Schiff base counterion is Glu113.^{6,7} Figure 3 shows the photointermediates of rhodopsin. In the initial photoreaction, the 11-*cis*-retinal in rhodopsin is isomerized to the all-*trans* form. The following thermal steps lead to the release of the retinal from the protein. Photoactivation of rhodopsin leads to interaction with a heterotrimeric guanine nucleotide-binding protein (G-protein) on the intracellular side of the membrane. The activated G-protein then triggers the further steps that ultimately lead to the hyperpolarization of the plasma membrane that initiates a nerve impulse. In its seven-helix structure and embedded ligand, rhodopsin is believed to be representative of G-protein-coupled receptors generally, a class which includes the signal transducers for acetylcholine, dopamine, glycoprotein hormones, and peptides.⁸ While rhodopsin is the rod cell pigment responsible for low-light vision, other retinal proteins in the cone cells are responsible for color vision. For these pigments the action spectrum is of obvious functional importance. In general, the visible spectra of rhodopsins are red shifted relative to the 440 nm absorption maximum of

protonated retinal Schiff bases in methanol. Because this bathochromic shift is due to the protein environment, it is known as the 'opsin shift'.⁹ The mechanisms by which the opsins 'tune' the chromophore has been one of the central issues in research on retinal proteins. The particularly large opsin shift in bacteriorhodopsin (to 568 nm) has made it a particularly interesting case even though it is not a visual pigment.

2 NMR STRATEGIES

Although NMR studies have also been made of fragments, here we will focus on studies of intact retinal proteins. These large integral membrane proteins are amenable to different NMR approaches depending on their manner of preparation. In solubilized form, they can be studied by solution techniques, with the caveats that the large protein-detergent complexes have relatively long rotational correlation times and that functional integrity cannot be assayed in the absence of a membrane. For membrane preparations, solid state techniques are required and have the potential of providing additional information from anisotropic interactions. In the crystalline native membrane, bacteriorhodopsin does not diffuse, which is ideal for solid state spectroscopy. With the exception of a few initial studies of lyophilized samples, purple membranes are normally studied as wet ultracentrifuge pellets which are frozen as needed to trap photointermediates (see below) or improve the signal-to-noise ratio. Rhodopsin, reconstituted in lipids after purification, undergoes slow rotational diffusion about an axis perpendicular to the plane of the bilayer. Since such motion interferes with cross polarization and decoupling, it is quenched for solid state NMR studies by lyophilization or freezing.

The large size of these systems makes selective isotopic labeling essential. For studies of the chromophore, the native retinal can be replaced by a synthetic isotopomer:¹⁰ the sample is bleached by treatment with hydroxylamine (which breaks the Schiff base linkage and releases retinal oxime) and then the pigment is regenerated by incubation of the sample with synthetic retinal in the appropriate conformation. Labeling of the opsins relies on bacterial or in vitro expression systems. In the case of bacteriorhodopsin, biosynthetic labeling is practical for those amino acids that the *Halobacteria* do not synthesize in excess. Attempts to isolate auxotrophic strains for the other amino acids have been successful only for arginine.¹¹ In one NMR study, an auxotroph of *Escherichia coli* was used to express selectively labeled bacteriorhodopsin, which was then purified and reconstituted in lipids.¹² So far, in vitro expression of bacteriorhodopsin¹³ has not been achieved on a scale relevant for NMR. For rhodopsin, it has so far proved impossible to prepare NMR quantities of properly folded protein either in cultures or in vitro. NMR studies of rhodopsin have therefore been restricted to the chromophore, with the exception of a recent study of a labeled fragment of G-protein bound to rhodopsin.¹⁴

For the most part, isotopic labeling of retinal proteins has taken the form of selective enrichment of naturally rare isotopes. This has the advantage of minimizing perturbation of the molecule. Thus, most NMR studies have made use of selective substitution of ¹³C for ¹²C, ¹⁵N for ¹⁴N, and ²H for ¹H. However, NMR nuclei have occasionally been

Figure 3 Photoproducts of bovine rhodopsin and their wavelengths of maximum visible absorbance. The chromophore is isomerized from 11-*cis* to all-*trans* in the initial photoreaction. Metarhodopsin II is the form that activates the G-protein. The isomerized chromophore is subsequently released and recycled by the cell

introduced less conservatively, by substitution of ^{19}F for ^1H .¹⁵ Most studies up to this point have made use of dilute spin systems; however, increasing attention is now being given to measurements of dipolar interactions between spin pairs to obtain internuclear distances. In ^{13}C studies the large natural-abundance signal generally makes the spectrum difficult to interpret, even with selective isotopic enrichment. Thus, in ^{13}C studies, it has become routine to subtract the spectrum of a natural-abundance sample from the spectrum of the labeled sample obtained under the same conditions (particularly spinning speed).¹⁶

In order to understand the molecular mechanisms of light transduction in retinal proteins, it is necessary to study their photointermediates. Time-resolved NMR studies have not been possible because of the very high optical density of the large samples required. Thus, NMR studies of photointermediates have relied on cryotrapping. In bacteriorhodopsin, pure bR₅₆₈ obtained by light adaptation can be stabilized for the duration of an NMR experiment by cooling to -5°C . The only intermediates of the bR₅₆₈ photocycle that have so far proven accessible are one of the M-intermediates and the N-intermediate. The M-intermediate is trapped alone in guanidinium hydrochloride at pH 10, which slows the M to N transition of the photocycle. These conditions are justified by the fact that the proton pump, which is the focus of interest, still functions, albeit relatively slowly. In NaCl at pH 10, the N-intermediate accumulates along with the M-intermediate. In both of these preparations, cooling to -40°C suffices to stabilize the intermediates for the duration of an NMR experiment. In rhodopsin, NMR studies have been conducted on the bathorhodopsin¹⁷ and metarhodopsin II¹⁸ intermediates, by cooling below 120 and 130 K, respectively.

3 STRUCTURE

3.1 Chromophore

In the earliest studies, retinal conformations were determined by analysis after chemical extraction. Although this procedure is relatively safe for the C=C configurations, it is not useful for single bonds, which are free to rotate when the chromophore is liberated from its binding pocket. It is also not useful for the C=N bond, which is broken on extraction. In situ studies have made use of resonance Raman spectroscopy and NMR spectroscopy. Of these, NMR has the advantage of avoiding any possible perturbation by light.

Initial NMR studies made use of the sensitivity of ^{13}C chemical shifts to steric interactions of directly bonded protons: electron density driven from the proton produces a low-frequency shift at the carbon. This effect was first identified for a retinal pigment in [12- ^{13}C] retinal-labeled bacteriorhodopsin. In the dark-adapted state, the spectrum showed a doublet with a low-frequency:high-frequency stoichiometry similar to the accepted 60:40 stoichiometry of bR₅₅₅:bR₅₆₈.¹⁹ Upon light adaptation to form pure bR₅₆₈, the low-frequency signal disappeared, confirming the assignment of signals originally made by stoichiometry.²⁰ These observations supported previous evidence for 13-*cis* and all-*trans* chromophores in bR₅₅₅ and bR₅₆₈, respectively. However, a doublet with similar

stoichiometry was also seen in dark-adapted [14- ^{13}C]retinal-labeled bacteriorhodopsin.²¹ Again, the low-frequency signal disappeared on light adaptation.²⁰ These observations suggested that the chromophores of bR₅₅₅ and bR₅₆₈ are 13-*cis*,15-*syn* and all-*trans*,15-*anti*, respectively. According to this interpretation, a corresponding steric effect should also be seen at C- ϵ of Lys216. These expectations have recently been confirmed in studies of [ϵ - ^{13}C]Lys-labeled bacteriorhodopsin, with a doublet in the dark-adapted state and disappearance of the low-frequency signal on light adaptation.²² Although the chemical shift data are thoroughly self-consistent, the most unambiguous determination of the C=N configuration has been made by rotational resonance studies of [14- ^{13}C]retinal,[ϵ - ^{13}C]Lys-labeled bacteriorhodopsin. The rate of magnetization exchange between the two carbons indicated an internuclear distance of 0.3 ± 0.02 nm in bR₅₅₅ and 0.41 ± 0.03 nm in bR₅₆₈, as expected for C=N *syn* and *anti* configurations, respectively.²³ This spin pair has also been revisited recently in a 2D rf-driven recoupling (RFDR) experiment in which the interactions can be observed in bR₅₅₅ and bR₅₆₈ simultaneously.²⁴ In this case, the more rapid development of cross-peak intensity for the low-frequency signals clearly demonstrates that these are associated with the shorter internuclear distance and steric interaction.

Steric interactions also play an important role at the other end of the chromophore. Retinal in solution comprises a rapidly exchanging mixture of the skewed 6-*s-cis* and planar 6-*s-trans* conformations, with the former dominating. The planar 6-*s-trans* conformation (shown in Figure 1) has the advantage of the extended planar π -system, but it has two methyl groups in close proximity to C-8. In the skewed 6-*s-cis* conformation the planar π -system is truncated, but only one methyl group is near C-8. Since the length of the π -system is an important factor for color discrimination, the 6-*s* conformation of the bound chromophore has received considerable attention. Studies of the 6-*s-cis* and 6-*s-trans* crystal forms of retinoic acid demonstrated that the ^{13}C -5 shift is sensitive to isomerization of the 6-*s* bond, as expected given the changes in steric interactions.²⁵ Interestingly the effect is entirely in the most high-frequency tensor element which moves 20 ppm to high frequency on 6-*s-cis* to 6-*s-trans* isomerization.

In [5- ^{13}C]retinal-labeled bacteriorhodopsin, the most high-frequency and most low-frequency tensor elements were found to correspond exactly to that of 6-*s-trans*-retinoic acid, suggesting that the chromophore in bacteriorhodopsin is the 6-*s-trans* form.²⁶ (The middle tensor element will be discussed in Section 4.1.) Complementary evidence for a 6-*s-trans* conformation in bacteriorhodopsin was obtained from the ^{13}C -8 chemical shift, which is also affected by the changes in steric interactions.²⁶ Steric interactions also influence the dynamics of the methyl groups, and the ^{13}C -18 longitudinal relaxation time in bacteriorhodopsin was found to be more typical of a 6-*s-trans* chromophore than a 6-*s-cis* conformation.²⁶ More recent ^2H NMR measurements of the activation energy for threefold hopping of the C-18 methyl group are also consistent with a 6-*s-trans* chromophore and inconsistent with a 6-*s-cis* chromophore.²⁷ Again, however, the most unambiguous determination of the 6-*s* conformation has been made by rotational resonance studies of doubly labeled bacteriorhodopsin. In [8,18- ^{13}C]retinal-labeled bacteriorhodopsin, the slow rate of magnetization exchange indicated a 6-*s-trans*

Figure 4 Solid state ^{13}C MAS difference spectra obtained by subtraction of a spectrum of natural-abundance bacteriorhodopsin from spectra of $[\epsilon\text{-}^{13}\text{C}]\text{Lys}[^{14}\text{-}^{13}\text{C}]\text{retinal}$ -labeled bacteriorhodopsin in the M-state.³¹ (a) The CP MAS difference spectrum. The ^{13}C -14 signal is to high frequency. There are two ^{13}C - ϵ signals, the stronger low-frequency signal is from the six free lysine residues. The smaller signal is from Lys216, which forms the Schiff base with the retinal. (b)–(d) The $n = 1$ rotational resonance difference spectra for magnetization exchange between $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ and $[^{14}\text{-}^{13}\text{C}]\text{retinal}$ at mixing times of 0.2, 5.0 and 20.0 ms, respectively

conformation²⁸ with an internuclear distance of 0.41 nm.²⁹ In $[8,16/17\text{-}^{13}\text{C}]\text{retinal}$ -labeled bacteriorhodopsin the average internuclear distance was found to be 0.33–0.35 nm, also consistent with a 6-*s-trans* conformation.²⁹

Analogous studies have been conducted of the M-state that is trapped at pH 10, in 0.3–0.5 M guanidinium hydrochloride or 0.1 M NaCl, when bR₅₆₈ is illuminated with light of wavelengths > 540 nm, at low temperatures.^{22,30,31} The ^{13}C -5 chemical shift indicates that the 6-*s* bond is still *trans*.³⁰ The ^{13}C -12 chemical shift confirms that the chromophore is 13-*cis*. The ^{13}C -14 and $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ chemical shifts indicate that the Schiff base configuration is still *anti*.^{22,30} This was confirmed by rotational resonance (Figures 4 and 5), which gave a 14- ϵ internuclear distance of 0.39 ± 0.01 nm, as expected for a C=N *anti* configuration and 0.1 nm larger than expected for a *syn* configuration.³¹ These results are consistent with interpretations made of resonance Raman spectra.³²

Similar studies have been made of the N-intermediate, cryotrapped with the M-intermediate in 0.1 M NaCl at pH

Figure 5 The observed and simulated magnetization exchange between $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ and $[^{14}\text{-}^{13}\text{C}]\text{retinal}$ in the M-state, under the $n = 1$ rotational resonance condition.³¹ - - -, 0.38 nm; —, 0.39 nm; — · —, 0.40 nm

10.³³ The 6-*s* conformation was not investigated, but the ^{13}C -12 chemical shift showed that the chromophore is still 13-*cis*, and the ^{13}C -14 and $[\epsilon\text{-}^{13}\text{C}]\text{Lys216}$ chemical shifts showed that the Schiff base remains in the C=N *anti* configuration. These results agree with the conclusions of time-resolved resonance Raman studies of the N-intermediate at room temperature.³⁴

Carbon-13 chemical shifts have also been used to characterize the rhodopsin chromophore. As in bacteriorhodopsin, the ^{13}C -14 chemical shift indicates that the Schiff base is C=N *anti* in rhodopsin³⁵ and bathorhodopsin.¹⁷ Whereas the bacteriorhodopsin chromophore has been found to be 6-*s-trans*, a 6-*s-cis* conformation is indicated by the ^{13}C -5 chemical shift in rhodopsin,^{35–37} and the ^{13}C -8 chemical shift in bathorhodopsin.¹⁷ Other ^{13}C chemical shifts are generally similar to those in the corresponding retinal Schiff base model compounds (11-*cis* for rhodopsin and all-*trans* for bathorhodopsin). Interestingly, those deviations that are observed are localized in the region of the chromophore that was identified in retinal analog studies as interacting with a protein charge.^{17,36,37} Perturbations in this region have also been detected by ^{19}F NMR of rhodopsin-containing fluorinated retinals.¹⁵

While bond isomerization determines the orientations of different parts of the chromophore relative to each other, it is also important to determine absolute orientations, especially for vectorial transport. Ulrich et al.³⁸ have used the quadrupole splittings of ^2H labels in uniaxially oriented films of bacteriorhodopsin to examine the orientation of the ionone ring relative to the membrane normal. Using the ^{31}P NMR spectral line-shape to determine the mosaic spread of the sample, and treating the ionone ring as a rigid unit, ^2H spectral lineshapes of oriented $[2,4,4,16,16,16,17,17,17,18,18\text{-}^2\text{H}_{11}]$ retinal-labeled bacteriorhodopsin, at various inclinations to the magnetic field,

were simulated for various ionone ring orientations. The fit to the experimental series of ^2H spectra was optimal for an ionone ring orientation that places the methyl groups on C-16, C-17, and C-18 at angles of 94, 75, and 46°, respectively, relative to the membrane normal. Given the known tilt of the chromophore, with the Schiff base closer to the cytoplasmic side and the ionone ring closer to the extracellular side, the ^2H analysis indicates that the C-18 methyl group points toward the cytoplasmic side of the membrane. This means that, for a fully planar all-*trans*,15-*anti* or 13-*cis*,15-*syn* chromophore the Schiff base proton or lone pair points toward the extracellular surface (as found for bR₅₆₈ in linear dichroism experiments³⁹), while for a fully planar 13-*cis*,15-*anti* chromophore the Schiff base proton or lone pair points toward the cytoplasmic surface.

3.2 Protein

Isotopic labeling of the opsin in NMR quantities has so far only been possible for bacteriorhodopsin. In this system, both secondary structure and tertiary structure have been addressed in a variety of ways.

The peptide backbone was first labeled by Lewis et al.,⁴⁰ in the carbonyls of the leucine residues, because these hydrophobic residues were expected to be buried in the membrane on the basis of their location in the hydrophobic stretches of the peptide sequence that were expected to form the transmembrane segments. The spectrum of intact [$1\text{-}^{13}\text{C}$]Leu-labeled purple membrane showed a rigid-lattice carbonyl powder pattern which indicated that, at the Leu residues, the peptide backbone was immobile on the ^{13}C NMR timescale even at 40°C. When the labeled bacteriorhodopsin was solubilized and reconstituted in DMPC (dimyristoyl phosphatidylcholine) vesicles above the lipid phase transition temperature, the spectrum was narrowed by fast rotational diffusion. Analysis of the motionally averaged lineshape was used to determine the possible orientations of the Leu peptide bonds relative to the diffusion axis. The data were found to be consistent with α_1 helices tilted at 20° from the membrane normal, a model that is congruent with electron density information.²

Bowers and Oldfield⁴¹ also studied [$1\text{-}^{13}\text{C}$]Leu-labeled purple membrane, and found a mobile component. Mobile components were also found for purple membranes $1\text{-}^{13}\text{C}$ labeled in Gly, Ile, Lys, Phe, and Val residues. For each amino acid except Val, the proportion of mobile residues was correlated with the proportion of residues in the C-terminus, suggesting that the C-terminus is mobile on the ^{13}C NMR timescale. Since the C-terminus does not contain any Val residues, it was suggested that the observation of mobile Val residues indicates another mobile region in protein. The discrepancy between these results for Leu and those of Lewis et al., described above, has not been solved.

Helgersson et al.⁴² have considered the chemical shifts of peptide carbonyl atoms. Based on homopolymers, in which the carbonyl carbon resonance is found at 176 ± 1 ppm for helical structures and 171 ± 1.5 ppm for nonhelical structures, they concluded that about 85% of Leu, 75% of Val, and 80% of Lys residues in bacteriorhodopsin are in helical regions. Less quantitatively, but more generally, Engelhard et al.⁴³ have noted that the chemical shift of the peak of the natural-abundance peptide signal in bacteriorhodopsin suggests a largely α -helical secondary structure. These results are consistent with the electron density distribution in bacteriorhodopsin.²

Seigneuret and co-workers have labeled the peptide backbone at the carbonyl carbons of the Phe⁴⁴ and Met⁴⁵ residues. Narrow, well-resolved signals were obtained by solubilizing in *n*-dodecylmaltoside. For the [$1\text{-}^{13}\text{C}$]Met-labeled bacteriorhodopsin, sequence specific assignments were obtained by selective colabeling of neighboring amino acid residues with ^{15}N and by papain proteolysis. Using these assignments, it was determined that, of the nine Met residues, only Met32, Met68, and Met163 are water exposed (as reflected in susceptibility to H_2O_2 oxidation) and weakly hydrogen bonded (as indicated by deuterium exchange from $^2\text{H}_2\text{O}$). These results are also consistent with the current structural model of bacteriorhodopsin.²

Deber et al.⁴⁶ focused on the secondary structure at proline peptide bonds, which are thought to play an important role in transport proteins. [$\gamma\text{-}^{13}\text{C}$]Pro-labeled bacteriorhodopsin was solubilized in $\text{CHCl}_3\text{:CD}_3\text{OD}$ (1:1) with 0.1 M LiClO_4 . Sufficient resolution was achieved to distinguish the 2 ppm difference in ^{13}C chemical shift between a *cis* and a *trans* X-Pro peptide bond. No *cis* signal was observed, and it was concluded that all 11 X-Pro peptide bonds in the solubilized bacteriorhodopsin are in the *trans* conformation. Further evidence has been supplied by an analogous solid state NMR study.⁴⁷ The chemical shift difference between C- β and C- γ of a proline residue is 7–11 and 3–5 ppm when the X-Pro peptide bond is *cis* and *trans*, respectively. The MAS spectrum of [$\beta,\gamma\text{-}^{13}\text{C}$]Pro-labeled bacteriorhodopsin showed only *trans*-configured X-Pro peptide bonds.

The Pro peptide bonds have also been studied by ^{15}N solid state NMR of [^{15}N]Pro-labeled purple membranes. Five well-resolved peaks are obtained at room temperature for the 11 Pro residues.⁴⁸ Less resolution is obtained at lower temperatures, suggesting that disorder is being frozen in. In order to assign the Pro91 signal, a REDOR experiment was carried out on a [$1\text{-}^{13}\text{C}$]Thr,[^{15}N]Pro-labeled sample, which has only one $^{13}\text{C}\text{--}^{15}\text{N}$ spin pair, between Thr90 and Pro91.⁴⁹ As shown in Figure 6, a single signal is obtained for Pro91 in bR₅₆₈. Figure 6 also shows a REDOR difference spectrum for a mixture of the bR₅₆₈ and M forms of bacteriorhodopsin. The spectrum clearly reveals a difference in the Pro91 ^{15}N chemical shift, providing direct evidence for a structural change in that part of the protein.

Nitrogen-15-labeled bacteriorhodopsin was also studied by heteronuclear $^1\text{H}\text{--}^{15}\text{N}$ coherence spectroscopy in methanol/chloroform (1:1) solution with 0.1 M NH_4CHO_2 .⁵⁰ In a uniformly ^{15}N -enriched sample, less than half of the cross peaks expected from the amino acid sequence were observed. By selective labeling and proteolytic cleavage, it was determined that the $^1\text{H}\text{--}^{15}\text{N}$ cross peaks were exclusively from the first two and the last helices in the sequence. Dynamic processes were inferred in the other four helices of the solubilized protein.

The protein structure has also been studied from the vantage point of the amino acid side chains. Initial studies of the mobilities of different side chains using ^2H NMR found a significant proportion of mobile residues that were attributed to surface groups.^{51–54} However, other investigations suggested that the mobile residues were largely due to contamination by residual plasma membrane.⁵⁵ More direct measures of surface exposure have made use of paramagnetic broadening in solubilized [^{13}C]methyl-labeled bacteriorhodopsin⁵⁶ and photochemically induced dynamic nuclear polarization of aromatic signals in ^1H NMR studies of solubilized natural-abundance

Figure 6 Nitrogen-15 MAS spectra for [1- ^{13}C]Thr,[^{15}N]Pro-labeled bacteriorhodopsin.⁴⁹ (a) CP MAS spectrum in the light-adapted state. (b) REDOR MAS spectrum in the light-adapted state. (c) The difference between spectra (a) and (b), showing only the signal from Pro91 (the only Pro bound to Thr) in the light-adapted state. (d) REDOR difference spectrum as in part (c) but for a mixture of the light-adapted and M states to show the change in the Pro91 chemical shift

bacteriorhodopsin.⁵⁷ Arseniev et al.⁵⁸ attempted to detect interactions between tryptophan residues in [5- ^{19}F]Trp-labeled bacteriorhodopsin solubilized in $\text{CD}_3\text{OH}/\text{CHCl}_3$ (1:1) with 0.1 M LiClO_4 . No such interactions were observed, but effects on different signals in the ^{19}F spectrum were noted upon addition of formic acid, reduction of the Schiff base, and modification of the retinal ionone ring. In similar studies of [3- ^{19}F]Phe-labeled bacteriorhodopsin, a distance of 1.3 ± 0.1 nm was measured between Phe230 and a spin label introduced at Met163.⁵⁹

4 PROTONATION AND HYDROGEN BONDING

Changes in protonation are obviously critical along the proton transport pathway in bacteriorhodopsin. As it happens, a protonation change is also at the heart of signal transduction

in rhodopsin.⁶⁰ Chemical shifts are excellent probes of protonation, and have been used to good advantage in studies of both bacteriorhodopsin and rhodopsin.

4.1 Schiff Base

Model compound studies show that chemical shifts of the odd-numbered carbon atoms of a retinal Schiff base are sensitive to the protonation of the Schiff base,²⁵ as expected based on the resonance structures which redistribute the positive charge from the Schiff base to the odd-numbered carbon atoms. The sensitivity is greatest at the C-13 position and, for rhodopsin studies which are so far limited to labels on the retinal, the ^{13}C -13 chemical shift is the clearest indicator of the protonation of the Schiff base. After some early false starts due to difficulties in replacing natural-abundance retinal with labeled retinal,^{61–63} Mateescu obtained the first ^{13}C NMR spectra for [13- ^{13}C]retinal-labeled samples of rhodopsin and bacteriorhodopsin.^{64,65} In both proteins, the ^{13}C -13 chemical shift indicated a protonated Schiff base. The ^{13}C -11 chemical shift also provided evidence for a protonated Schiff base in bacteriorhodopsin.¹⁹ In more recent work, the ^{13}C -13 and ^{13}C -15 chemical shifts obtained for bathorhodopsin are consistent with a protonated Schiff base in this photointermediate,¹⁷ and those obtained for metarhodopsin II indicate a deprotonated Schiff base in this activated state.¹⁸ In bacteriorhodopsin, the ^{13}C -13 chemical shifts correspond to a deprotonated Schiff base in the M-state³⁰ and a reprotonated Schiff base in the N-state.³³

However, the ^{15}N chemical shift of the Schiff base is by far the most sensitive probe of protonation,⁶⁶ and in bacteriorhodopsin, where it is possible to label the protein, the solid state ^{15}N NMR spectrum of [ϵ - ^{15}N]Lys-labeled bacteriorhodopsin provides the definitive determination of the protonation state of the Schiff base. Such spectra for dark-adapted bacteriorhodopsin were reported independently by Mateescu et al.⁶⁵ and by Harbison and co-workers.^{66–69} With a good signal-to-noise ratio, the spectrum shows a doublet due to the coexistence of bR₅₆₈ and bR₅₅₅ in a dark-adapted sample.^{66–69} Solid state ^{15}N NMR spectra have also been obtained for [ϵ - ^{15}N]Lys-labeled bacteriorhodopsin cryotrapped in the M- and N-states. The [ϵ - ^{15}N]Lys chemical shifts indicate that the Schiff base is deprotonated in the M-state and reprotonated in the N-state.³³

From the start, it was noted that the ^{15}N chemical shifts in bR₅₆₈ and bR₅₅₅ are still further to low frequency than normal for protonated retinal Schiff bases, and it was suggested that this is due to an unusually weak counterion.⁶⁶ Comparison of the shift tensor elements for different retinylidenebutylimine salts⁷⁰ and retinylideneanilinium salts⁷¹ has shown that the lowest-frequency element is insensitive to counterion strength, and the two high-frequency elements vary proportionately. The same relationship is observed between the tensor elements for bacteriorhodopsin, strengthening the association of the ^{15}N chemical shift with counterion strength.⁷⁰ However, the effect is more extreme in bacteriorhodopsin, indicating a counterion that is weaker than any halide, carboxylate, or phenolate moiety that might be available as a simple counterion in a protein. In order to explain the data it became necessary to postulate a complex counterion, involving water-mediated hydrogen bonding between the Schiff base and protic amino

acid residues.⁷⁰ Such a hydrogen-bonded complex would diffuse the counterion charge over several bonds. The complex counterion is consistent with the current structural model of bacteriorhodopsin, which locates water, two Asp residues and one Arg residue in the vicinity of the Schiff base.²

Interestingly, weakening the strength of the Schiff base counterion also affects the ¹³C-5 chemical shift at the other end of the polyene chain.^{71,72} In the retinylideneanilinimine salts, which crystallize in the planar 6-*s-trans* conformation, the effect shows up essentially exclusively in the middle element of the ¹³C-5 chemical shift tensor, and the unusually weak Schiff base counterion in bacteriorhodopsin completely explains the unusual value of the middle element of the ¹³C-5 chemical shift tensor in bacteriorhodopsin.⁷¹ A weak Schiff base counterion also destabilizes the ground electronic state of the chromophore relative to the excited state, and thereby constitutes an important mechanism for the bathochromic opsin shift. This effect is larger in the retinylideneanilinimine salts, which crystallize in the planar 6-*s-trans* conformation, than in the retinylidenebutylimine salts, which crystallize in the skewed 6-*s-cis* conformation.⁷¹ This enhancement is also seen in solution in 1,1-didemethylretinal Schiff bases, which adopt a planar 6-*s-trans* conformation, compared with retinal Schiff bases in which the planar 6-*s-trans* conformation is sterically disfavored.⁷² The synergistic effects of the extended π system, due to ring-chain planarization, and the weak Schiff base hydrogen bonding, due to the complex counterion, are sufficient to explain completely the very large opsin shift in bacteriorhodopsin.⁷¹

With HCl titration, the visible absorption maximum of bacteriorhodopsin shifts from 568 nm (at pH ~7) to 605 nm (at pH ~2), and then reverts to 565 nm (at pH ~0). Spectra of [ϵ -¹⁵N]Lys-labeled samples indicated that the ¹⁵N chemical shift is closely correlated with the color.⁷³ A 16 ppm low-frequency shift in the blue species indicates an even weaker Schiff base counterion than in the two purple species. This is consistent with the expected protonation of an acidic residue in the complex counterion at low pH. The recovery of the color and ¹⁵N chemical shift at still lower pH is thought to be due to the replacement of a water molecule in the complex counterion by chloride from the bulk acid. Carbon-13 NMR results for selectively enriched polyene carbons in bR₆₀₅ revealed that the chromophore conformation is generally not very different from that of bR₅₆₈, although the spectrum of [14-¹³C]retinal bR₆₀₅ showed doublets for the 15-*syn* and 15-*anti* forms that may reflect the coexistence of 13-*cis* and all-*trans* conformers in each case.⁷³

4.2 Polar Amino Acid Residues

Amino acids capable of ionization or hydrogen bonding could participate in proton transport in bacteriorhodopsin. Roles proposed for Tyr and Asp residues have motivated NMR studies of these groups.

Tyrosinate is an unusual species, but FTIR and UV studies suggested that it existed in bacteriorhodopsin. Since the [4'-¹³C]Tyr chemical shift is sensitive to deprotonation of the adjoining oxygen, it provides an unambiguous probe for long-lived tyrosinate. However, MAS NMR spectra of [4'-¹³C]Tyr-labeled bacteriorhodopsin showed no detectable long-lived tyrosinate in dark-adapted bacteriorhodopsin at pH bulk

values below 13,⁷⁴ light-adapted bacteriorhodopsin at pH = 7 or 10,⁷⁵ or the M-state at pH = 10.⁷⁵ It was concluded that the changes in Tyr residues detected by FTIR and UV spectroscopy represented changes in hydrogen bonding rather than deprotonation.

Internal Asp residues certainly do play a direct role in proton transport. Engelhard et al.⁴³ biosynthetically labeled bacteriorhodopsin with [4-¹³C]Asp. Unexpected scrambling of the label to Trp was found, but this signal causes no problem because it appears in a distinct region of the spectrum. On the other hand, the signals of the nine labeled Asp residues and the three labeled Asn residues are superimposed on peptide backbone signals due to natural-abundance ¹³C and some scrambling through the tricarboxylic acid cycle to [1-¹³C]Glu. Nevertheless, six resonances were resolved. These were considered in terms of five categories: exposed Asp residues which must be deprotonated, buried Asp residues that are not protonated, buried Asp residues that are protonated, Asn residues in polar environments, and Asn residues in nonpolar environments. The signals due to surface Asp residues were assigned to high-frequency resonances by comparison of the spectrum of the native membrane with that obtained after 'deionization' (ion exchange chromatography to replace the intrinsic cations of the purple membrane with protons). Based initially on chemical shifts and ¹⁴N line-broadening effects in model compounds, the two most narrow, lowest frequency lines were assigned to protonated Asp residues which must be buried. The protonated state of these low-frequency resonances was later confirmed by estimation of the middle chemical shift tensor element from sideband intensities.⁷⁶ Specific assignments for the Asp96 and Asp85 signals were subsequently obtained by studies of site-specific mutants.⁷⁷ By elimination, based on the current structural model of bacteriorhodopsin and FTIR studies of Asp residues, the other narrow low-frequency signal was assigned to Asp115.⁷⁶ Based on the current structural model of bacteriorhodopsin and the functional properties of site-specific mutants, Asp85 and Asp212 are expected to be influenced by light adaptation. This prediction was borne out: two signals shifted on light adaptation, including the previously assigned Asp85 signal and a signal further to high frequency which was assigned to Asp212 by elimination.⁷⁶ The signals of all four internal Asp residues have thus been assigned in bR₅₅₅ and bR₅₆₈. Using these assignments to interpret the spectrum of the M-intermediate in the D96N mutant, deprotonation of the Schiff base is seen to lead to protonation of Asp85 while Asp212 remains protonated.⁷⁸ Deionization of the membranes was also found to induce protonation of Asp85.⁷⁸

5 PROTON DIFFUSION

Among the various forms of spectroscopy that have been applied to bacteriorhodopsin, NMR has the unique potential to chart the movement of protons, which is central to the energy transduction process. One approach makes use of the relatively fast relaxation of the immobile protons of the protein.⁷⁹ In this CP MAS experiment, cross polarization is delayed until ¹H magnetization remains only in the bulk water. Under these circumstances, the only nuclei that are cross polarized effectively are those that exchange protons with bulk water on the submillisecond timescale. Using this

selection technique for [ϵ - ^{15}N]Lys-labeled bacteriorhodopsin, Harbison et al.⁷⁹ observed cross polarization of the Schiff base and the six free Lys residues, although there was no longer any cross polarization of the natural-abundance ^{15}N in the peptide backbone. By varying the delay, it was demonstrated that proton exchange between the Schiff base and bulk water is essentially complete in about 0.5 ms. Delayed cross polarization has also been applied to [^{15}N]Arg-labeled bacteriorhodopsin.^{80,81} In this case, rapid proton exchange was only observed at high pH.⁸¹

Proton NMR provides a more direct means of following proton movement. Zheng et al.⁸² have shown that high-resolution 2D ^1H MAS NMR spectra can be obtained by using ^2H to dilute and cross polarize the protons. This approach was used to obtain 2D ^1H NOESY spectra of chemically exchanging solids, and the development of cross-peak intensities was analyzed to extract the kinetic constants for exchange. Proton exchange was found to occur preferentially along hydrogen bonds. Initial 2D ^1H NOESY spectra have also been obtained for perdeuterated bacteriorhodopsin.⁸³ Signal intensity from the residual nonexchanging protons on the protein prevents detailed examination of the signals of the exchanging protons. However, the 2D spectrum shows the expected exchange among high-frequency absorbing protons and, on a somewhat longer timescale, unexpected exchange between high-frequency and low-frequency protons. The latter are believed to be water molecules in nonpolar pockets. This interpretation is supported by parallel ^2H studies of water dynamics, which show a small population of freely rotating water molecules even at very low temperatures where hydrogen bonding would inhibit rotation.⁸³ Although these experiments are the first to find evidence for water in hydrophobic regions of purple membranes, such water has been suggested to fill gaps between polar amino acids along the proton transport pathway.

1 INTRODUCTION

In biological systems, there are three species of significance that have major isotopes with nuclear spin- $\frac{3}{2}$. These are mainly present as monovalent aquo ions. They are $^{23}\text{Na}^+$ and $^{35}\text{Cl}^-$, which are mostly extracellular, and $^{39}\text{K}^+$, which is concentrated in the cytoplasm. The NMR signal from the first is much stronger than those from the other two. In fact, it is weaker than only the $^1\text{H}_2\text{O}$ resonance and, in some regions, the ^1H signal from fat.¹ We have recently reviewed the study of these ionic resonances,² and have cited 20 other reviews of this much investigated subject. The great interest stems from two tantalizing possibilities. The first is that the dominance of the quadrupolar relaxation mechanism for the NMR signals of these spins can allow a sensitive characterization of the molecular environments in which they find themselves. The second is that NMR could offer a noninvasive way of monitoring the transcytolemmal concentration gradients of these species, the energies of which are the sources of their main biochemical roles.¹ The facts that the compartmental resonances of each of these species are isochronous have hindered realization of both of these goals.

2 TYPES OF SPIN-3/2 SPECTRA

The isolated spin- $\frac{3}{2}$ nucleus provides for a one-spin, four-level system. This can manifest itself in four different types of spectra, depending on the nature of the spin dynamics and the nature of the molecular environment. Figure 1 shows rotating frame energy level diagrams and actual one-pulse single quantum (SQ) ^{23}Na spectra exemplifying each of these four types. The classification is one we proposed in 1988.³ Thus, the *type-a spectrum* (on the right in Figure 1) is a single-crystal-like spectrum. There is at least a *residual* EFG projection present at the nucleus that causes shifts in the level

energies and the average spectroscopic splitting factor, $\bar{\omega}_Q$, to be nonzero. The areas of each of the two satellite peaks is 0.3, relative to that of the center peak of 0.4. Even though the three population differences (between states with adjacent levels) are essentially equal at Boltzmann equilibrium, the NMR signal intensity measures this difference as weighted by the magnetic moment *projection* of the state.⁴ This is the lowest spin quantum number for which unequal peaks areas are manifest. Although the type-a spectrum in Figure 1 looks like that of a true single crystal, the value of $\bar{\nu}_Q$ (~ 17 kHz) is one or two orders of magnitude smaller. It is actually the motionally narrowed spectrum from an oriented liquid crystal. The same relationship is true for the *type-b spectrum* in Figure 1, which looks like that of a true microcrystalline powder, but is actually that of an unoriented liquid crystal. It is, nonetheless, an inhomogeneous spectrum, as far as the satellite transitions are concerned. The *type-c spectrum* is a ‘homogeneous’ (‘biexponential, super-Lorentzian’) spectrum, in which the satellite peaks have essentially coalesced into a single, broad, homogeneous peak which is effectively isochronous with the narrower center peak.² Again, $\frac{3}{2}$ is the lowest spin quantum number for which this kind of spectrum can occur. Finally, the *type-d spectrum* is the extreme narrowed case, represented in Figure 1 by a ^{23}Na spectrum from an aqueous solution of NaCl.

3 THE DEBYE MODEL

One can understand the progression from a type-d spectrum to a type-a spectrum in terms of a random fluctuation of the EFG tensor strength and/or orientation that can be described with a single correlation time, τ_c —this is the Debye model.² Thus, the type d spectrum obtains when τ_c is much smaller than the Larmor period, ω_L^{-1} (ω_L is the Larmor frequency), usually of the order of nanoseconds. In this case, $\bar{\omega}_Q$ is zero, even if the fluctuations of the EFG projection are quite large (for the ^{23}Na aquo ion itself, ν_Q^{rms} is about 1 MHz but τ_c is less than picosecond²). As τ_c increases and passes through ω_L^{-1} , the spectrum changes from type d to type c. In this case, however, $\bar{\omega}_Q$ remains zero. If τ_c continues to increase, the fluctuation becomes slower, and passes through $(\omega_Q^{\text{rms}})^{-1}$, the value of $\bar{\omega}_Q$ becomes nonzero and the spectrum changes from type-c to type-b or type-a, depending on the macroscopic order of the sample. If the sample is disordered, say a powder with a random distribution of the orientations of the EFG tensor, then a type-b spectrum emerges. A simulation of a spectrum evolving from type-c to type-b with the lengthening of a single τ_c is shown in Figure 2 (Figure 1 of Eliav et al.⁵). The values of τ_c are: 10^4 ns, 10^3 ns, 80 ns, and 20 ns [panels (a)–(d), respectively]. A clear type-b spectrum is seen in panel (a). Because the value of ν_Q is so (unrealistically) large (12.5 MHz), a clear type-c spectrum is observed only for the case when τ_c is 20 ns [panel (d)], and a second-order frequency shift of the center peak is seen in the insets in Figure 2. If the simulation had been for a completely ordered sample, say a single crystal with a unique site, then a type-a spectrum would have emerged in panel (a).

The Debye model is conceptually the simplest for the quadrupolar relaxation mechanism. It has been found, however, that it is inconsistent with experimental observations on the ^{23}Na resonances from such seemingly simple systems as

Figure 1 Rotating frame energy level diagrams for isolated $I = \frac{3}{2}$ systems. Four types of motionally narrowed SQ spectra are possible (a, b, c, and d). Representative ^{23}Na spectra are seen below each of the energy level diagrams. The type-d spectrum is that of NaCl in H_2O . The type-c spectrum is that of Na^+ in an aqueous solution that has a high concentration of micelle-solubilized gramicidin channels. The type-b and type-a spectra are of Na^+ in aqueous suspensions of unoriented and oriented dodecyl sulfate micelles, respectively. (Reproduced from W. D. Rooney and C. S. Springer, Jr., *NMR Biomed.*, 1991, **4**, 209)

suspensions of pure bovine serum albumin in saline solution⁶ and agarose gel soaked in saline solution (see *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*). Thus, it is not surprising that it also does not apply to the intracellular or extracellular ^{23}Na signals from suspensions of yeast cells.⁶

4 DISCRETE EXCHANGE MODELS

Very popular models that can sustain more complexity than the Debye picture have invoked equilibrium chemical exchange between two distinct sites that have different quadrupolar properties. These sites can be characterized by their location in the Debye continuum.² Thus, *James–Noggle exchange*⁷ is that between two different type-d sites and can yield only a type-d spectrum as a resultant. *Bull exchange*⁸ is that between a type-d site and a type-c site and can yield either type of resultant spectrum, depending on the lability of the exchange on the timescale determined by the properties of the two sites. *Chan exchange*⁹ is that between a type-d site and a type-a site. It can produce a type-c resultant spectrum, as well as a type-d or a type-a spectrum, depending on the lability of the exchange, or a type-b spectrum if there is a random orientation distribution of the type-a sites, which are

otherwise identical. A very informative simulation of a Chan exchange equilibrium, showing all three resultant spectra that appear as a function of the exchange lifetime, is shown in Figure 3. (Figure 2 in Eliav et al.⁵). Here, there are equal populations of a Debye type-d site (with $\nu_Q = 0.3 \text{ MHz}$ and $\tau_c = 0.1 \text{ ns}$) and a Debye type-a site [with (again) $\nu_Q = 12.5 \text{ MHz}$ and $\tau_c = 4 \times 10^3 \text{ ns}$]. Since there is a random distribution of the orientations of the latter, a clear type-b spectrum of this population is observed at the longest exchange time, $5 \times 10^4 \text{ ns}$ (bottom). The exchange time shortens on going up Figure 3. When $\tau_{ex} = 10 \text{ ns}$, a type-c resultant spectrum is seen. When $\tau_{ex} = 0.001 \text{ ns}$ (top), a type-d resultant spectrum is manifest. It is important to note, however, that the isothermal James–Noggle, Bull, or Chan two-site exchange models each have six independent parameters (the relative population of one site, the values of ω_Q^{rms} for each site, the values of τ_c for each site, and the preexchange lifetime in one site). If temperature-dependent data are fitted, the number of parameters rises to at least eight.

Interpretations using discrete exchange models (DEMs) are always couched in terms of true chemical ‘binding’ of the ion in the more severe (in the quadrupolar sense) site; that which is type-c or type-a. This is true whether the exchange is fast or relatively slow. This may be realistic in some model situations, in which a characterized, real binding site is present

in some quantity. For example, the type-c spectrum in Figure 1 is that of Na^+ in an aqueous solution that has a high concentration of micelle-solubilized gramicidin channels.¹⁰ However, in tissue, the concentration of well-defined binding sites is much, much less than the concentration of ions.² This is why DEM fittings of tissue data always result in a very small population in the bound site (1% or less) but with very severe quadrupolar properties (large ν_Q^{rms} and/or τ_c) required to achieve agreement. An additional problem for tissue is that though the concentration of known binding sites for these ions is tiny, the kinds of binding sites are varied. A three-site exchange model¹¹ requires at least 13 independent parameters. Analyzing the tissue situation with a realistic DEM is rather untenable.

It would be fortunate if some other mechanism dominated. Thus, it is significant that residual quadrupolar splitting has been observed for systems (co-ions and noble gases)² in which it is highly unlikely that there can be discrete binding sites.

5 THE BERENDSEN MODEL

In 1973, Berendsen and Edzes¹² described a model that seems to us to be much more realistic. We have elaborated on it.^{2,6} It focuses first on the EFG tensor projection fluctuations caused by motions of the inner hydration shell of the ion. As pointed out above, for the $^{23}\text{Na}^+(\text{aq})$ ion, these are very powerful and very rapid. Superimposed on these are slower modulations, usually also of lower amplitudes, which are generated as the aquo ion diffuses about and encounters macromolecules and/or lipid assemblies. These low-frequency modulations could simply be due to distortions of the inner hydration shell during outer-sphere collisions with the macromolecules. These would surely be more frequent than occurrences of actual inner-sphere binding to macromolecular loci, though the latter would also modulate the EFG. The preponderance of negative fixed charges found on natural macromolecules and lipid assemblies could serve to increase the occurrence of inner sphere complexation in the cases of $\text{Na}^+(\text{aq})$ and $\text{K}^+(\text{aq})$, but it could just as well increase the frequency of outer-sphere collisions by increasing the effective concentrations of the mobile cations in the diffuse double layers. The very rapid inner-sphere fluctuations are ignored in Figure 1, but the slow modulation of the level energies is suggested for the type-c diagram.

To complete the picture of the Berendsen mechanism, one needs the concept of a sample *domain*, as experienced by a diffusing aquo ion. A domain must be at least as large as the average volume sampled by the diffusional excursions during the lifetime of an NMR coherence. The RMS three-dimensional random walk distance can be estimated [$r^{\text{rms}} = (6Dt)^{1/2}$] if a value for the diffusion coefficient, D , is assumed. The diffusion time, t , might be taken to be the time for the

Figure 2 A spectral simulation of the Debye model. There is only one site, with $\nu_Q = 12.5$ MHz, but with a random distribution of orientations. The values of τ_c are: 10^4 ns (a), 10^3 ns (b), 80 ns (c), and 20 ns (d). A type-b spectrum is seen in (a) and a type-c spectrum is seen in (d). The value of ν_L is 94.5 MHz. The insets depict the center peak. (Adapted from Figure 1 of U. Eliav, A. Baram, and G. Navon, *J. Chem. Phys.*, 1988, **89**, 5584)

coherence to fall to 10% of its initial value (i.e. $t = 2.3 T_2$). If the diffusion is isotropic, then the minimum domain is a sphere with a radius of r^{rms} . Now, the fluctuations of the inner hydration sphere are certainly isotropic. However, a macromolecule appears as a more or less two-dimensional surface to a diffusing ion. The distortion caused by its encounter is not isotropic but has a direction; the normal to the surface in the simplest picture. If the surface normals encountered in the average NMR diffusional volume of an ion are not randomly oriented (relative to B_0), then the slow fluctuation will be anisotropic, and will not average to zero.

The type-a and type-b spectra shown in Figure 1 were obtained from suspensions of cylindrical dodecyl sulfate micellar liquid crystals.^{2,3,6} Figure 4 illustrates the Berendsen model for these situations. A sample domain is suggested as a region enclosed by heavy lines. Within each domain in these liquid crystalline samples, the micelle cylinders are shown as being completely parallel. In Figure 4(a), the cylindrical axes in all domains are parallel to each other, and to B_0 , in this case. Although a $\text{Na}^+(\text{aq})$ ion is free to diffuse in the aqueous space between the cylinders (an average NMR diffusion volume is less than the size of a domain), the micellar surfaces it encounters all have their normals perpendicular to B_0 . Thus, the slow modulation is never averaged to zero. Although the diffusional motion considerably narrows the spectrum from what it would be for a single crystal with Na^+ bound to a dodecyl sulfate head-group (splitting, probably of the order of megahertz), it remains perfectly single-crystal like. This is because the sample of oriented liquid crystals has macroscopic order as well as microscopic order. Berendsen and coworkers first reported this in 1971 with oriented, hydrated DNA fibers (ref. 3 in Berendsen and Edzes¹²). Figure 4(b) depicts a similar situation, except that the liquid crystalline domains are no longer oriented. Although there remains microscopic order within a domain [it is identical to that in Figure 4(a)], and thus each domain is of type-a, the viewer is to imagine a random distribution of the cylindrical axes from different domains, i.e. macroscopic disorder. This would give rise to the inhomogeneous broadening of the satellite peaks seen in the type-b spectrum in Figure 1, provided the true sample domains are large enough relative to the average NMR diffusion volume that interdomain exchange is sufficiently slow. The ensemble of these domains should still be considered a single population, in the chemical sense. In this picture, there is really no such thing as a type-b domain; if there is intradomain disorder, a type-c spectrum results.

What about the Berendsen model for the type-c spectrum? Figure 4(c) illustrates a small region of human blood at one million times magnification (for the original), such that only macromolecules are shown. The water and monovalent aquo ion molecules are omitted for clarity. Let us concentrate initially on the extracellular (plasma) space [top of Figure 4(c)] where Na^+ is concentrated. For a $^{23}\text{Na}^+$ spin out in the bulk

Figure 3 A spectral simulation of the Chan discrete exchange model. There are equal populations of a Debye type-d site ($\nu_Q = 0.3 \text{ MHz}$, $\tau_c = 0.1 \text{ ns}$) and a Debye type-a site ($\nu_Q = 12.5 \text{ MHz}$, $\tau_c = 4 \times 10^3 \text{ ns}$). There is a random distribution of orientations of the latter. Thus, it gives rise to a type-b spectrum at the longest exchange time ($5 \times 10^4 \text{ ns}$; bottom). The value of the exchange time τ_{ex} is given for each spectrum. The left panels show the center peak(s). (Adapted from Figure 2 of Eliav et al.⁵)

of the plasma well away from the external erythrocyte surface, the macromolecular surfaces it may encounter in its diffusional excursions are apt to have randomly oriented normals. The average distance between these surfaces is about 10 nm (100 Å). It has been demonstrated that ^{23}Na spectra from dense suspensions of more or less globular proteins and polymeric gels in saline are of type-c.^{6,15,16} (See also *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*.) Thus, in addition to the rapid modulations of the inner hydration sphere, the slow fluctuation of the EFG by diffusion is also isotropic, and averages to zero.

It is much more difficult to make an explicit statement of the Berendsen model than of a DEM. Nevertheless, this has been done in the form of continuous diffusion models (reviewed by Rooney and coworkers^{2,6}), models with distributions of τ_c values,^{2,6,17} and what appears to be a Debye model with a distribution of ω_Q^{rms} values.¹⁸

6 EXPERIMENTAL DISCRIMINATION OF SPECTRAL TYPES

Step 2 of the comprehensive approach we suggested in 1991² was the determination of the *spectral type* of each resonance. Inspection of the one-pulse SQ spectra displayed in 1 would lead one to imagine that this is straightforward. Such is rarely the case, however, for at least two reasons. First, the extremely high signal-to-noise (S/N) values evident in Figure 1 are really quite necessary for the discrimination of the type-b, -c, and -d spectra seen there. The second reason is that the inhomogeneous width of the type-b spectrum shown in Figure 1 is quite large compared with the intrinsic linewidths for the spectral peaks of those liquid crystalline samples (see the type-a spectrum). Recently, it has been found that some more-biological systems, and some human tissues in vivo yield type-b spectra with very small inhomogeneous widths, which are quite similar to the intrinsic spectral linewidths.^{15,16,18–20} (A DEM interpretation of these results would require the existence of at least one Chan exchange equilibrium.) Effecting this determination requires the creation of the double- or triple-quantum (DQ or TQ) coherences (denoted by 2Q and 3Q on the type-c diagram in Figure 1), which are (indirectly) detectable for all but the type-d spectra.

The description of multiple quantum coherence experiments on these single (isolated) spin, four-level systems with spherical (irreducible) tensor bases for the density matrix operators has proved to be most informative (see *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*). These tensor operators are often represented by

Figure 4 Illustrations depicting sample domains that give rise to the various spectral types according to the Berendsen model. (a, b) Domains in liquid crystalline samples comprising cylindrical micelles. In (a), the domains are all oriented, parallel to B_0 , in this case, and, in fact, by B_0 for the micelles giving rise to the type-a spectrum in Figure 1. In (b) the domains are to be considered as randomly oriented. This would give rise to a type-b spectrum. (c) A small portion of human blood, 118 nm $\times$ 228 nm (1180 Å $\times$ 2280 Å), containing a region of plasma (top) and erythrocyte cytoplasm (bottom), separated by a section of cytolemma and cytoskeletal network (middle). [(a,b) Modified from Khetrapal et al.¹³; (c) reproduced from D. S. Goodsell,¹⁴ *Am. Sci.*, 1992, **80**, 457]

Table 1 Spectral Types and Spherical Tensor Representations

Tensor	Type			
	d	c	b	a
$\mathbf{T}_{00}$	A	A	A	A
$\mathbf{T}_{10}$	A	A	A	A
$\mathbf{T}_{20}$	–	–	A	A
$\mathbf{T}_{30}$	–	A	A	A
$\mathbf{T}_{11}$	D	D	D	D
$\mathbf{T}_{21}$	–	–	I	I
$\mathbf{T}_{31}$	–	I	I	I
$\mathbf{T}_{22}$	–	–	I	I
$\mathbf{T}_{32}$	–	I	I	I
$\mathbf{T}_{33}$	–	I	I	I

^aA, accessible; D, directly detectable; I, indirectly detectable.

the symbols, $\mathbf{T}_{li}$, where l is the rank (statistical multipolar order) and i is the component (coherence order).² The rank index, l , conveys information about the eigenstate populations,²¹ while the order index, i , describes the coherent superpositions of eigenstates. In the present case, the l index can take all integral values from 0 to 3 and the i index can take all integral values from 0 to $\pm l$. In this article, when we give an i value we mean it to represent $\pm i$. Table 1 indicates which eigenstate populations are accessible and which coherences are directly and indirectly observable for the four spectral types. Figure 5 depicts the eigenstate populations $\mathbf{T}_{00}$, $\mathbf{T}_{10}$, $\mathbf{T}_{20}$, and $\mathbf{T}_{30}$, the type-a and type-b single quantum spectra that are detected when $\mathbf{T}_{11}$ evolves from the $\mathbf{T}_{21}$ coherence, and the type-a, type-b, and type-c single quantum spectra that are detected when $\mathbf{T}_{11}$ evolves from the $\mathbf{T}_{31}$ coherence.

Jaccard et al.²³ were the first to point out that, though the third rank tensors are accessible to $I = \frac{3}{2}$ spins displaying type-a, -b, or -c spectra, the second-rank tensors are not accessible to type-c spins (Table 1, Figure 5). Thus, they suggested the demonstration of $\mathbf{T}_{21}$ as a clear proof of type-a or type-b. They proposed editing the spectrum by passage of the magnetization through a DQ filter designed to annihilate all but that from the $\mathbf{T}_{21}$ coherence. The absence in $\mathbf{T}_{11}$ from $\mathbf{T}_{21}$ (Figure 5) of the center peak present in $\mathbf{T}_{11}$ (Figure 1) aids in the inference that $\mathbf{T}_{21}$ existed.

Kemp-Harper and Wimperis^{19a} have argued in favor of displaying the absorption/emission singly antiphase mode of $\mathbf{T}_{11}$ from $\mathbf{T}_{21}$ shown in Figure 5, because of the resemblance the dispersion mode type-b spectrum from singly antiphase $\mathbf{T}_{21}$ (see 1 in Eliav and Navon¹⁸) can bear to the absorption/emission mode spectrum arising from doubly antiphase $\mathbf{T}_{31}$ for either type-c or type-b (Figure 5) when the inhomogeneous width is similar to the intrinsic linewidth, apparently a common situation. However, when one has the superposition of spectra from both the $\mathbf{T}_{21}$ and $\mathbf{T}_{31}$ representations of a single population of type-b or type-a spins, the two spectral components cannot be simultaneously phased in their absorption/emission modes. They are shown this way in Figure 5 primarily for their pedagogical value in reflecting the relative eigenstate populations.

Employing experiments of this kind, Navon and coworkers^{18,20} and Kemp-Harper and Wimperis^{19a} have examined ²³Na spectra from bovine cartilage, which may serve as a

model for interstitial extracellular space, the primary locus of tissue Na⁺. These two groups each find that there is at least one population of Na⁺ giving rise to a type-b spectrum, although the experimental results depend on the exact nature of the cartilage. Nasal cartilage gives rise to a residual splitting $2\bar{\nu}_Q$ of 550 (± 76) Hz,¹⁸ while the articular leg or ligament cartilage yields a value almost an order of magnitude greater.^{19a} The major macromolecular constituents of cartilage are proteoglycan and collagen fiber polymers, the former bearing a significant net negative fixed charge.²⁰ Eliav and Navon found that hydrated collagen fiber powder could yield a broader type-b spectrum than their cartilage sample.¹⁸ The fact that a ‘soluble form of denatured collagen’ (gelatin) does not give a type-b spectrum¹⁸ suggests that the microscopic order experienced by the ²³Na spins is ‘associated with the helical structure of the collagen fiber’. It is possible that the cylindrical liquid crystalline micelles suggested in Figure 4(b) model this situation. In the actual liquid crystals represented in Figure 4(b), however, the parallel cylinders within a domain can be as close as 10 nm (100 Å),⁶ depending on the extent of hydration, and thus can give rise to such values of $2\bar{\nu}_Q$ as the 34000 Hz observed the type-b spectrum in Figure 1. It seems most likely that the residual splitting produced by microscopic order in a Berendsen domain is proportional to the degree of *parallelity* (to coin a new word) in the macromolecular structure and inversely proportional to the *spacing* of the more or less parallel surfaces. Thus, one may expect very large splitting from the extracellular Na⁺ in cell junction gaps, where the degree of parallelity is very high and the adjacent exterior cell surfaces can come within 2.7 nm (27 Å) of each other, over an area very large on the microscopic scale.²⁴

Although there is less Na⁺ inside cells, the intracellular ²³Na (Na_i) signal has also been studied with DQ and TQ filtering techniques. Shinar et al.¹⁵ and Tauskela and Shoubridge¹⁶ have each found at least one population of Na⁺ inside human erythrocytes that gives rise to a type-b spectrum. The two laboratories agree that the residual splitting is very small: $2\bar{\nu}_Q$ is 40–50 Hz; the spectrum is almost type-c. From various ancillary experiments, they also agree in the suspicion that the type-b spectrum arises from the interaction of Na⁺ with the intact cytoskeletal network comprising the spectrin and actin proteins. A portion of this network is seen just inside the section of cytoplasmic membrane depicted in Figure 4(c). Of course, the cytoskeletal network also gives rise to the unusual biconcave discoid shape of the erythrocyte, which brings the internal faces of the cytolemma, and the network, to within about 1500 nm (15000 Å) of one another at the closest point—the disk diameter is about 7700 nm (77000 Å).^{25a} Thus, it is not clear whether it is simply the shape of the cells or direct interaction with the network that is the source of the type-b spectrum. The fact that there is at least one population of extracellular Na⁺ (Na_o) in the erythrocyte pellet that also exhibits a type-b spectrum ($2\bar{\nu}_Q \approx 25$ Hz) argues in favor of the former.¹⁶ The interior of each cell could be considered as one, large type-a domain. If it were possible to orient the cells all in one direction, and thus to produce macroscopic order, the spectra of these Na_i populations should become type-a. This still would not completely settle the issue, however, because the cytoskeletal networks from all the cells would also have been macroscopically ordered. Experiments have not yet ruled out the existence of an additional Na_i population, in

slow exchange, that exhibits a type-c spectrum. Such studies constitute step 3 of our comprehensive approach.²

Disk-shaped and rod-shaped cells have some degree of parallelity, which they impose on their intracellular and extracellular (in a pellet) spaces, though the spacing may be quite large on the microscopic scale. What about the situation for spherically shaped cells? If the cell is large enough such that the curvature of the surface is small relative to the average NMR diffusional volume, a Na^+ aquo ion near the cytolemma would sense a distinct orientation of the surface normal, as if it were in a type-a domain. However, there is absolutely no parallelity and the residual EFG dies away as the spin wanders away from the surface. It seems quite clear that out in the bulk of the cytoplasmic soup, the ^{23}Na nucleus experiences a microscopically disordered (isotropic) macromolecular environment. Figure 4(c) depicts a portion of the erythrocyte cytoplasm—the surfaces of the hemoglobin molecules, which constitute the vast majority, are about 5 nm (50 Å) apart, on average. The cytoplasm of other cells are quite similar, if one disregards the macromolecule variety.¹⁴ Recall the determinations of type-c spectra reported above for dense protein solutions not contained by a cytolemma. However, recent results suggest that the macromolecular variety can be quite important.^{25b}

Although we did not conduct the most sensitive test for type b (the DQ filter for $\mathbf{T}_{11}$ from $\mathbf{T}_{21}$ described above), we have studied the $^{23}\text{Na}_i$ signal from the yeast cell fairly exhaustively.^{2,6} Our results are quite consistent with a single population of Na^+ exhibiting a type-c spectrum. *S. cerevisiae* yeast cells are spherical with an internal diameter of about 5000 nm (50 000 Å).⁶ In the lifetime of the shortest transverse coherence for the $^{23}\text{Na}_i$ resonance, we estimated that the Na^+ aquo ion could sample an average NMR diffusion volume represented by a sphere with diameter of about 3400 nm (34 000 Å); i.e. less than the entire intracellular space.⁶ Since we do not see evidence of significant amounts of different populations of Na_i in slow exchange, the conclusion is that the microscopic environment is rather uniform throughout the cell. The huge ribosomal molecules¹⁴ are crucial in determining the type-c character of the $^{39}\text{K}_i$ resonance in *Escherichia coli*^{25b} and other ‘viable’ cells such as yeast.

The family of multiple quantum filtering techniques (reviewed in Rooney and Springer;² see also *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*) are most elegant for discriminating the spectral type and accurately measuring the relaxation rate constant (R ; there are six such constants and they are indicated on the energy level diagram for the type-c spectrum in Figure 1) values

Figure 5 Depictions of eigenstate populations ($\mathbf{T}_{00}$, $\mathbf{T}_{10}$, $\mathbf{T}_{20}$, and $\mathbf{T}_{30}$), and observable SQ coherences ($\mathbf{T}_{11}$) that evolve exclusively from higher rank spherical tensor representations of the density matrix ($\mathbf{T}_{21}$ and $\mathbf{T}_{31}$). For $\mathbf{T}_{00}$, $\mathbf{T}_{10}$, $\mathbf{T}_{20}$, and $\mathbf{T}_{30}$, the level splitting is analogous to that in Figure 1. The lengths of the horizontal lines represent the relative eigenstate populations. Adapted from Fig. 4. Halstead et al.²¹ The type-a coherences are adapted from 1 Sanctuary²². For the simulations of type-b coherences, that from $\mathbf{T}_{21}$ is reproduced with permission of S. Wimperis from Kemp-Harper et al.,^{19b} and that from $\mathbf{T}_{31}$ is reproduced with permission of G. Navon from U. Eliav and G. Navon¹⁸

necessary for the molecular interpretation of the resonance. However, since the multiple quantum coherences are formally forbidden, and must be detected indirectly, there is a signal intensity penalty associated with their use. The maximum intensity for the DQ-filtered T_1 experiment is 8% (measured by peak areas) while that for the DQ-filtered T_2 experiment is 15%, relative to the one-pulse SQ signal intensity acquired in the same time.² The DQ-filtered experiment for T_{21} described above has a maximum intensity of 10–12%.¹⁹ The TQ-filtered T_2 experiment has a maximum intensity of 22% (see *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*), but it does not discriminate type-b spectra from type-c ones (Table 1).^{19a} A Jeener–Broekaert experiment (which filters for T_{20} , just as diagnostic for type-b spectra, Table 1) is a little more sensitive than the T_{21} experiment.^{19a,b} The use of gradients for multiple quantum filtering (instead of phase cycling) is expected to yield even lower intensities.²⁶ Of course, these are *maximum* intensities. The results obtained in actual practice are even smaller.^{16,27} For example, Tauskela and Shoubridge¹⁶ found that the DQ-filtered T_2 intensity never rose above 2.5% in their studies of erythrocyte suspensions.

Following Pekar et al.,²⁸ there have been a number of schemes suggested for the use of multiple quantum filter experiments to discriminate compartmental signals from tissue samples. There are two aspects that make them less than ideal, however. The first is their reduced sensitivity. One hates to dispense with one order of magnitude of an already weak signal, especially in an in vivo and/or imaging situation; though this has been tried for the latter.^{29,30} The second aspect is that they do not quantitatively discriminate the compartments—because of the significant overlap of compartmental spectral types (see *Relaxation of Quadrupolar Nuclei Measured via Multiple Quantum Filtration*)—and end up requiring some shift or relaxation reagent anyway.

7 EXPERIMENTAL DISCRIMINATION OF SIGNALS FROM PHYSIOLOGICAL COMPARTMENTS

We now turn to step 1 of the comprehensive approach that we suggested in 1991.² It is interesting that the most recent developments in the oldest method make it the most sensitive and the most quantitative, if it can be conducted properly. This is the acquisition of one-pulse SQ spectra in the presence of a shift reagent (SR), a paramagnetic molecular anion. The membrane-impermeant SR species can enter only certain compartments and shift the resonance frequency of only the $^{23}\text{Na}^+$ and $^{39}\text{K}^+$ ions contained in those compartments. It does this due to a rapid chemical binding equilibrium with the monovalent cation. The SR approach was introduced, independently, by our laboratory³¹ and another³² in 1982. We reviewed the development of SRs in 1990.³³ Shachar-Hill and Shulman³⁴ as well as ourselves^{35a} have recently considered the difficult possibilities with regard to SRs for the resonance of the mostly extracellular $^{35}\text{Cl}^-$ aquo anion.

The initial demonstrations of the utility of SRs were with lipid vesicle and cell suspensions, and allowed monitoring of the transcytolemmal Na^+ gradient, in particular. We reviewed the literature of such studies in 1987.^{1,36} In 1985, we introduced the use of SRs for perfused ex vivo tissue, with the beating rat heart preparation.³⁷ Since that time, there

have been many semiquantitative studies of transmembrane Na^+ (and, to a lesser extent, K^+) transport. These have been reviewed in 1987³⁶ and 1989.³⁸ Important qualitative observations of fundamental aspects have been made using this approach. One is the discovery that extracellular Mg^{2+} blocks Na^+ influx into myocardial cells during Ca^{2+} -free perfusion of the rat heart.³⁹ Another is that the accumulation of Na_i^+ during global ischemia of the rat heart occurs via the Na^+/H^+ exchange transporter.⁴⁰ Moreover, the level of Na_i is a reasonable predictor of whether the heart will go into ventricular fibrillation during ischemia.⁴¹ An example from this latter work is shown in Figure 6 (M. M. Pike, personal communication). Figure 6(a) shows one-pulse SQ ^{23}Na spectra acquired in 50 s each from a heart perfused with 4 mM of the SR TmDOTP⁵⁻ before (control), and after 51 min of low-flow ischemia (during which beating was maintained). The unshifted resonance at zero ppm represents Na_i^+ . The large peak shifted 2.5 ppm to higher frequency by TmDOTP⁵⁻ represents Na_o^+ and, in this case, includes the large contribution from the effluent perfusate surrounding the heart in the NMR tube. The peak at about 8 ppm is that of Na^+ in a reference balloon, contained in the left ventricle and filled with 4 mM TmDOTP⁵⁻ in a Ca^{2+} -free saline solution. The Na_i level clearly increases during ischemia. The spectra in Figure 6(b) were obtained before, and after 51 min of ischemia in a heart that experienced ventricular fibrillation during the ischemia. Not only was the Na_i level higher just before ventricular fibrillation began (not shown), but it rises to a very high value during the ischemic period.

In 1986, Ingwall's laboratory introduced the study of localized in vivo ^{23}Na spectra obtained from a rat infused with SR.⁴² We reviewed such reports in 1993.^{43a} The Dallas group of Sherry and Malloy⁴⁴ has developed the TmDOTP⁵⁻ SR mentioned above [DOTP⁸⁻ represents 1,4,7,10-tetraazacyclododecane- N,N',N'',N''' -tetra(methylenephosphonate)], shown it to be the most effective, and demonstrated its potential for in vivo use. Figure 6(c) (similar to 2 in Bansal et al.^{44a}) shows the time dependence of interleaved in vivo one-pulse SQ $^{23}\text{Na}/^{31}\text{P}$ spectra obtained from the liver of a rat during a programmed, varied infusion of TmDOTP⁵⁻. The ^{31}P spectra demonstrate the maintenance of the energy state of the liver. The infusion time is shown in the left column and the cumulative SR dose in the next column. The ^{23}Na spectra, typically acquired in about 1 min each, show the development of a shift to high frequency of a portion of the resonance as the SR enters the liver. If the infusion is stopped, the spectrum will slowly revert to the preinfusion form as the SR is eliminated through the kidney and washed out of the liver.^{42b} The conventional wisdom is that the SR enters the entire extracellular space of the liver, where Na^+ is concentrated, and that the shifted peak represents Na_o , while the unshifted peak represents Na_i . Figure 6(d) shows localized ^{23}Na spectra from regions of interest in different organs, after infusion of TmDOTP⁵⁻.^{44b} The kidney shows an additional broad peak at very high frequency (about 32 ppm) due to Na^+ in the tubular filtrate, where the SR is concentrated in the process of its elimination. It appears that the SR enters the extracellular interstitial space in every major organ except the healthy brain, where it is constrained to the plasma space by the intact blood–brain barrier.^{35b} This is most important because it is the monitoring of the status of the transcytolemmal Na^+ gradient that is desired.

Figure 6 One-pulse SQ ^{23}Na spectra obtained from samples treated with a shift reagent (SR). (a,b) Spectra from ex vivo beating rat hearts perfused with TmDOTP $^{5-}$ (M. M. Pike, personal communication). They are similar to 4 in Pike et al.⁴¹ (a) Spectra of a normal heart before (bottom) and after (top) a period of global ischemia. (b) As (a), except for a heart that experienced ventricular fibrillation during ischemia. (c, d) In vivo spectra (A. D. Sherry, personal communication). (c) Localized spectra from a region of interest in the liver, as a rat is infused with TmDOTP $^{5-}$ beginning at time zero. SQ ^{31}P spectra, obtained with interleaved acquisition, are also presented. It is similar to 2 in Bansal et al.^{44a} (d) Spectra from regions of interest in various organs after a period of SR infusion (Reproduced from N. Bansal, in 'MR Pulse', Society of Magnetic Resonance, Berkeley, CA, 1994, 2.). (e) A simulation of SQ spectra obtained from nonbrain tissue containing SR. (Reproduced from W. D. Rooney and C. S. Springer, *NMR Biomed.*, 1991, 4, 209)

Although qualitative assessment of changes in this gradient is extremely useful, the possibility of quantifying it is so tantalizing that it has generated much effort. Unfortunately, the issue is not simple. Figure 6(e) is a simulation of an *in vivo* one-pulse SQ ^{23}Na spectrum from nonbrain tissue,² where each compartment is pictured as giving rise to a type-c spectrum and the component linewidths are estimated using transverse relaxation data from yeast cell suspensions.⁶ One must realize that the broad components correspond to small T_2 [$(R_{2f}^{1Q})^{-1}$, in Figure 1] values. These can be in the submillisecond range. If a T_2 value is sufficiently small compared to the receiver 'dead-time' in a one-pulse experiment, some of the signal has vanished even before the receiver has turned on. The situation is even worse for the delay in an echo-based experiment. This is the main source of the famous ^{23}Na 'visibility' problem.² For ^{23}Na in most cases, the T_2 of the center peak [$(R_{2s}^{1Q})^{-1}$, in Figure 1] is sufficiently large that it is always detected, and the visibility never falls below 0.40. For ^{35}Cl ^{9,34,35} and ^{39}K ,^{25b,45} which have been much less studied, it is not clear if this remains the case. Obviously, it is best to employ the smallest dead-time or echo delay that is experimentally possible.

Even if one succeeds in acquiring the entire signal, it is clear in Figure 6(e) that there is extensive overlap of the compartmental peaks, particularly their broad, coalesced satellite components. The accurate curve resolution of these from experimental spectra is an almost impossible task. Figure 6(e) suggests that one should fit only the upper portions of the sharp features with Lorentzian lineshapes, and then assume that these represent 0.4 of the intensities, respectively, from the Na^+ in those compartments.² It is important to note from Figure 1 that this assumption will be a good one whether a compartmental spectrum is type-c or type-b. It seems to us that this approach is the most sensitive and the most accurate for the tissue signal situation.

We have pointed out another quantitative feature of the SR approach.^{43a} With a relevant calibration curve, one can use the resonance frequency of the Na_o peak to estimate the instantaneous thermodynamic concentration of the SR; that in its actual volume of distribution. For example, using the appropriate calibration curve (of those in Figure 7 Albert et al.^{43a}), we estimate $[\text{TmDOTP}_o^{5-}]$ to be about 9 mM in the liver giving rise to the spectrum in Figure 6(d).

A qualitative advantage of the SR technique is that it can be used in combined spectroscopy and imaging experiments.^{46–48} In principle, one can resolve subvoxel Na_i and Na_o signals⁴⁹ and produce Na_i and Na_o maps (for all tissues except the brain) by spectroscopic imaging.

Thus, it is clear that the SR approach has many advantages. However, it also has problems, some of which almost certainly preclude its use in larger animals or humans. We mention five of these. (1) In cell suspension and perfused tissue studies, each TmDOTP^{5-} anion usually replaces five Cl^- anions (normally about 110 mM) in extracellular fluids. This could cause small perturbations in transmembrane Donnan potentials. (2) For *in vivo* experiments, Na_5TmDOTP is usually added to the blood. Thus, in the case above where TmDOTP_o^{5-} is 9 mM in the liver, there is an additional burden of 45 mM Na^+ in the extracellular space (an increase of about 30%). (3) The SR TmDOTP^{5-} has been found to extract Ca^{2+} from the body and into the blood (and the urine?),^{44b,c} since it interacts with Ca^{2+} , in addition to Na^+ .^{43a,b} Extra Ca^{2+} is added

to TmDOTP^{5-} -containing perfusion medium for beating rat hearts.^{44a} (4) Even if there were not toxicity concerns arising from the above facts, the amount of SR required makes it probably prohibitively expensive for use with large animals or humans. The maximum cumulative dose of SR shown in Figure 6(c) corresponds to 10 g of thallium (and 7 g of sodium) for a 75-kg human. (5) Finally, it would be particularly interesting to monitor the transcytolemmal gradient in the brain. However, the SR is denied access to the extracellular interstitium in the healthy brain by the intact blood–brain barrier [Figure 6(d)].^{35b}

We have recently considered an approach that may allow SR-free discrimination of compartmental ^{23}Na resonances.⁵⁰ This is to obtain the *relaxogram*, or distribution of relaxation times, that describes a relaxation decay data set; a study we refer to as *relaxography*.⁴⁹ Figure 7 shows a stacked plot of transverse relaxograms obtained from ^{23}Na FIDs of suspensions of canine erythrocytes at different hematocrit (hct) values acquired by our colleagues (Drs Y. Seo and M. Murakami), with a dead-time of 25 μs .^{50b} The abscissa is $\log T_2^*$ (T_2^* in milliseconds) and the oblique axis is hct. Although the erythrocyte Na_i signal may be slightly type-b (see above), it appears as effective type-c in these relaxograms. Two Na_i peaks are seen, with the area under the one at the larger T_2^* value averaging 0.67 of that of the one at the smaller T_2^* value.^{50b} The total area of these increases with increasing hct. Although the Na_o signal can become type-c or even slightly type-b at elevated hct values (see above), it appears as effective type-d (one peak) in the relaxograms shown in Figure 7, at least in those from lower hct values. The single Na_o resonance appears between the Na_i peaks, where they coexist, and its area decreases with increasing hct. It may have turned into effective type-c at hct = 0.66, just before it disappears, and may be incompletely resolved from the Na_i resonances. The signal-averaged FIDs for Figure 7 were acquired in about 5 min each. However, other results lead us to expect that FIDs of sufficient quality could be obtained in slightly less than 1 min each. The total area under all of the peaks in each relaxogram in Figure 7 is proportional to the amount of Na^+ within the

Figure 7 A stacked plot of transverse ^{23}Na relaxograms obtained from suspensions of canine erythrocytes at different hematocrit values. (Reproduced from J. H. Lee, Y. Seo, M. Murakami, C. Labadie, and C. S. Springer, in Abstracts of the 11th Annual Meeting of the Society of Magnetic Resonance Medicine, Society of Magnetic Resonance Medicine, Berkeley, CA, 1992, p. 2222)

NMR sensitive volume. It is in excellent agreement with an independent analysis for Na^+ .^{50b}

It remains to be seen whether ^{23}Na relaxography will be successful with true in vivo experiments. Relaxographic analysis involves the formal inverse Laplace transformation of the relaxation decay data set. This is a notoriously 'ill-posed' problem,⁴⁹ and it is not clear if the tissue situation produces parameters such that the transformation can be effectively carried out with the quality of data that can be obtained from the living organism.

8 ^{23}Na MR IMAGING

Although the ^{23}Na signal is the second strongest from tissue¹, it is still 4–5 orders of magnitude weaker than that of $^1\text{H}_2\text{O}$.¹ The small values of T_1 for ^{23}Na , due to the quadrupolar relaxation mechanism, allow more frequent excitation and ameliorate this problem, but only to a modest extent. Nevertheless, there has been persistent interest in producing images from the ^{23}Na resonance, even though an imaging protocol is always longer than a spectroscopic one.

All of the considerations given above are, of course, also important when generating and interpreting ^{23}Na images. For example, Thulborn and coworkers⁵¹ have found that significant intensity from the rat brain is lost if the dead-time (echo time, in this case) is increased from 0.5 to 2 ms. In accurate quantitative work, Thulborn's group⁵² has shown how to use the ratios of ^{23}Na to $^1\text{H}_2\text{O}$ voxel intensities to generate *concentration maps*. They find values narrowly centered about 45 mM in the normal rat brain. This is in good agreement with what is expected.¹ It is important to note, however, that this is a volume-weighted average value—as if Na^+ was uniformly distributed throughout the voxel. Of course, Na^+ is concentrated in the extracellular space (about 150 mM) and mostly excluded (about 10 mM) from the millions of cells in a voxel. Since it is this transcytolemmal gradient that is the main biological role for Na^+ , an important goal would be to map the gradient itself. This may be possible. We have shown above that the use of SRs allows the discrimination of Na_o and Na_i signals in most tissues of small animals, except the brain. Relaxographic analysis may allow SR-free discrimination, even in the brain, and in larger animals. In other work, we have shown that, at least with the use of a relaxation-catalyzing contrast agent in the extracellular space, relaxographic analysis also allows the discrimination and imaging of subvoxel $^1\text{H}_2\text{O}_o$ and $^1\text{H}_2\text{O}_i$ signals.⁴⁹ In principle, taking the corresponding ^{23}Na to $^1\text{H}_2\text{O}$ signal intensity ratios would allow the mapping of the thermodynamic values, $[\text{Na}_o^+]$ and $[\text{Na}_i^+]$. A map of the ratios of these quantities would be a concentration gradient map, and, with a reasonable assumption of activity coefficients, even an activity gradient map.

Acknowledgments

I thank my present and former graduate and undergraduate students as well as my collaborators (their names appear frequently in the references): they have made what I consider to be outstanding contributions to this subject. I also thank Ms Marie Dippolito for processing this manuscript and, in fact, almost all of our spin- $\frac{3}{2}$ papers. I thank Professors Gil Navon, Martin Pike, Dean Sherry, Keith Thulborn, Cees van Echteld, and Steve Wimperis, as well as Drs Hadassah Shinar, Uzi Eliav, and Joe Tauskela for sending reprints and preprints describing the most impressive work of their groups. Many of these individuals also provided critical readings of a draft of this article. I also thank the National Institutes of Health (Grant GM 32125) and Brookhaven National Laboratory (Laboratory Directed Research and Development Program Grant/co-PI, Joanna Fowler) for support during the preparation of this contribution.

1 INTRODUCTION

In molecules that experience anisotropic motion, the dipolar and quadrupolar interactions are not averaged to zero, resulting in residual splittings in their NMR spectrum. The best example of this phenomenon is of molecules dissolved in liquid crystals.

Most biological tissues, with the exception of body fluids, contain ordered structures such as membranes, fibrous proteins and nerve fibers. These structures can induce anisotropic motion to water and other molecules interacting with them, which is expressed in residual dipolar or quadrupolar interactions. In the single quantum (SQ) spectra of water molecules in biological tissues the splitting resulting from these interactions is masked by the strong isotropic signal of the bulk media. The advantage of the double quantum filtered (DQF) NMR is that it detects only molecules with residual quadrupolar or dipolar interactions and J couplings. Thus, the strong signal of the isotropic water molecules that do not have J splitting is filtered out.

The first application of DQF to the study of ordered biological systems was performed on ^{23}Na of sodium ions.¹ This topic, which was reviewed in the previous volumes of the Encyclopedia² as well as in some recent reviews,³ will not be dealt with in the present study. This article will concentrate on the applications of ^1H and ^2H DQF NMR to water molecules in biological systems.

2 THEORETICAL BACKGROUND

The basic double quantum filtered (DQF) pulse sequence is

$$90^\circ - \frac{\tau}{2} - 180^\circ - \frac{\tau}{2} - 90^\circ - t_{\text{DQ}} - 90^\circ - t_2 (\text{Acq}) \quad (1)$$

We use the notation of the irreducible spherical tensor operator $T_{l,p}$, where l is the rank and p is the coherence of the tensor with $|p| \leq l$. These tensors are composed of combinations of the more familiar spin operators I_z and $I_\pm = I_x \pm iI_y$. By using this representation the processes that take place during the pulse sequence are easily understood, while keeping in mind the following two simple rules: (a) a radiofrequency pulse can change the coherence p within the limits of $|p| \leq l$; (b) changes in the rank l can occur by relaxation and by quadrupolar, dipolar or J couplings, keeping the same value of p . Thus, in the DQF pulse sequence (equation 1), the first 90° pulse generates SQ coherences ($T_{1,\pm 1}$). During the time interval τ , denoted as the creation time, second rank tensors $T_{2,\pm 1}$ are formed by the residual dipolar or quadrupolar interactions. The 180° pulse in the middle of the creation time τ serves to refocus the chemical shifts and magnetic field inhomogeneities. The second 90° pulse converts the SQ coherences of the second rank tensors, $T_{2,\pm 1}$, into double quantum coherences ($T_{2,\pm 2}$), which evolve during the double quantum evolution time, t_1 . The last 90° pulse transfers the magnetization back to $T_{2,-1}$, which evolves into the detectable $T_{1,-1}$. The selection of the double quantum coherence pathway is accomplished by either a proper phase cycling⁴ or by the application of field gradients.⁵

For spin $I = 1$ nuclei or for a pair of dipolar coupled protons, with the residual interaction (quadrupolar or dipolar) being much greater than the relaxation rate (and the exchange rate for protons), the DQF free induction decay (FID) is given by:⁶⁻⁸

$$\text{FID} \propto \sin(\omega_i^L \tau) e^{-R_2 \tau} \sin(\omega_i^L t_2) e^{-R_2 t_2} \quad (2)$$

where ω_i^L is either the quadrupolar (ω_Q^L) or the dipolar (ω_D^L) residual interaction in the laboratory frame of reference (with the Z direction along the magnetic field) $R_2 = 1/T_2$ for $I = 1$ nuclei, and $R_2 = k/2 + 1/T_2$ (where k is the proton exchange rate) for protons. ω_i^L is given in terms of its value in the local director frame of reference ω_i^{loc} by the following transformation:

$$\omega_i^L = \alpha \omega_i^{\text{loc}} \frac{(3 \cos^2 \theta_{\text{LD}} - 1)}{2} \quad (3)$$

where θ_{LD} is the angle between the local director and the magnetic field, and $\alpha = 1$ for $I = 1$ and $\alpha = 3/2$ for a pair of protons.

As expected from a Fourier transform of $\sin(\omega_i^L t_2)$ the lineshape of the DQF spectra is composed of an antiphase pair of lines separated by $2\omega_i^L$ (Figure 1). The antiphase presentation of the DQF spectra is sometimes inconvenient. In order to obtain a presentation where all the peaks have the same phase, the pulse sequence denoted as IP-DQF⁸ (Figure 2), where a reconversion process is introduced after the DQF step, can be used.

In biological tissues we frequently encounter situations with a distribution of the residual interactions. From equation (2) one can predict that the DQF spectra will show an increasing number of peaks ('wiggles') when the creation time τ is increased. The splitting between those peaks, in completely

Figure 1 Calculated DQF spectral lineshapes as a function of $R = \omega_D^L T_2$. (a, c) $R = 40.0$; (b, d) $R = 3.0$; (a, b) are given in a absorption mode; (c, d) are given in a dispersion mode

Figure 2 The in-phase DQF (IP-DQF) pulse sequence. (Reproduced from Ref.⁸)

disordered tissue, is only a function of τ and is given by $1/\tau$ (Hz).⁷

^1H NMR spectra of water in ordered biological tissues differ from those of ^2H spectra due to the effect of proton chemical exchange. This effect is responsible for the coalescence of the dipolar-split proton spectrum into a single line upon raising the temperature.^{9,10} This is in contrast with the ^2H spectrum, whose splitting is not sensitive to temperature.

The dependence of the DQF signal on the residual dipolar interaction and proton exchange rate has recently been calculated.⁸ For the two cases of (a) $k < 2\omega_D^L$, and (b) $k > 2\omega_D^L$, the expressions for the DQF signal are given by:

$$\text{FID} \propto \frac{2\omega_D^2}{r^2} e^{-R_2\tau} \sin r\tau e^{-R_2\tau_2} \sin rt_2 \quad (k < 2\omega_D^L) \quad (4a)$$

$$\text{FID} \propto \frac{2\omega_D^2}{\rho^2} e^{-R_2\tau} \sinh \rho\tau e^{-R_2\tau_2} \sinh \rho t_2 \quad (k > 2\omega_D^L) \quad (4b)$$

where

$$\rho = \frac{\sqrt{k^2 - 4\omega_D^2}}{2}, \quad r = \frac{\sqrt{4\omega_D^2 - k^2}}{2}$$

Clearly for very slow proton exchange ($k \ll 2\omega_D^L$) the expression in equation (4a) converges into equation (2). On the other hand for very fast exchange ($k \gg 2\omega_D^L$) provided that $\tau, \tau_2 \gg 1/k$, one obtains:

$$\text{FID} \propto \left(\frac{\omega_D^L}{k}\right)^2 e^{-\tau/T_2^e} e^{-\tau_2/T_2^e} \quad (5)$$

$$\frac{1}{T_2^e} = \frac{(\omega_D^L)^2}{k} + \frac{1}{T_2}$$

Equation (5) clearly shows that $1/T_2^e$ is orientation dependent and that the intensity of the DQF spectra decreases as (ω_D^L/k^2) . As the water proton exchange rate is similar in the different tissues, the main reason for the contrast between them is the differences in the values of ω_D^L .

Warren et al.¹¹ have shown that DQF and zero quantum filtered (ZQF) NMR signals can also be formed by intermolecular dipolar interaction between very distant protons. This effect depends on two factors. (a) A large magnetization that results in non-negligible contributions to the equilibrium density matrix of tensors with ranks higher than one (for instance $T_{2,0}$). Such large magnetization can result from either high concentrations of the spins or from a high magnetic field. (b) A mechanism for the conversion of high-rank, single quantum tensors (such as $T_{2,-1}$) to the observable $T_{1,-1}$. The last process is enabled by the presence of field gradients or by a non-spherical geometry of the vessel. Intermolecular DQF and ZQF have been used to obtain a new contrast in MR images of the brain.¹² Typically, the time scale of these processes is

Figure 3 SQ and DQF ^2H NMR spectra at 76.8 MHz of rat sciatic nerve equilibrated in deuterated saline. (Adapted from Ref.¹³)

tens of milliseconds, depending on the gradient strength. Thus, it can be neglected in tissues where the intramolecular dipolar interaction causes relaxation on a much shorter time scale, such as tendon and cartilage.

3 ^2H DQF NMR STUDY OF WATER COMPARTMENTATION AND DIFFUSION IN RAT SCIATIC NERVE

Peripheral nerves comprise three types of tissues: the endoneurium, the epineurium and axons. The first two tissues contain collagen fibers, while axons are thin tubes with an inner diameter of a few micrometers, wrapped in many layers of myelin sheath. The ^2H single pulse spectrum of a rat sciatic nerve equilibrated in deuterated saline¹³ (Figure 3) consists of a very strong peak and two pairs of satellite transitions, which can be observed upon magnification of the spectrum. The central transition is mostly due to free D_2O molecules. The satellites represent D_2O molecules in anisotropic environment having a non-zero residual quadrupolar splitting. The ^2H DQF NMR spectrum of the same nerve is composed of three quadrupolar-split water signals. The signal of the isotropic water, which is most pronounced in the single pulse spectrum, is eliminated by the DQF pulse sequence and a very narrow signal, which evolves at longer creation times, is revealed. On the basis of the time course of the shifts of the different water signals caused by the addition of CoEDTA^{2-} or CoCl_2 and on the basis of the action of collagenase, the signals with peak to peak splittings of about 470 (A), 120 (B) and 9 (C) Hz were assigned to water in the endoneurium, epineurium, and the intra-axonal compartment, respectively.¹³ Each of the satellite signals has a characteristic dependence on the creation time τ (Figure 4). Fitting this dependence to equation (2) indicates that the contribution of the quadrupolar splitting to the peak to peak separation in the narrow intra-axonal signal, is only 6 Hz, and the rest is due to T_2 relaxation rate.

By performing the DQF experiment at different values of τ , the properties of the water in each compartment can be studied independently. One such property is the water diffusion in nerves. It has attracted a lot of attention since the development of diffusion weighted imaging of the brain.

Figure 4 Peak intensity of the three different signals shown in Figure 3, as a function of the creation time, τ . (Reproduced from Ref.¹³ by permission of Academic Press)

^2H diffusion measurements for water in the rat sciatic nerve was performed¹⁴ by the DQF pulsed gradient spin echo (DQF-PGSE) sequence:¹⁵

$$90^\circ - \frac{\tau}{2} - 180^\circ - \frac{\tau}{2} - 90^\circ - t_3 - \delta - t_4 - 180^\circ - t_3 - \delta - t_4 - 90^\circ - \text{Acq} \quad (6)$$

In this pulse sequence the two gradient pulses of duration δ are applied during the DQ evolution time, and thus the

Figure 5 Diffusion coefficients, D_{app} , of deuterated water in an excised rat sciatic nerve equilibrated in deuterated saline measured at 46.0 MHz as a function of the diffusion time Δ . D_0 , diffusion gradients parallel to the nerve axis and D_{90} , perpendicular to the nerve axis. For the axon, creation time $\tau = 30$ ms and time to echo $TE = 60$ ms. For the endoneurium and epineurium, $\tau = 0.6$ ms and $TE = 16$ ms. The D_{90} solid line for the axon is a fitted curve based on Ref.¹⁶ with a diameter of $6.0 \mu\text{m}$ and $D_0 = 1.20 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$. (Reproduced from Ref.¹⁴ by permission of Wiley InterScience)

effective gradient strength is doubled. Also, since the ^2H DQ relaxation time of water molecules is much longer than T_2 , the measurements can be performed at longer diffusion times and smaller gradient strengths.

The apparent diffusion coefficients at each diffusion time were calculated from the attenuation of the echo as a function of the gradient strength.¹⁴ The water diffusion coefficients in all three compartments were found to be anisotropic. Anisotropic diffusion of water in the endoneurium and epineurium may result from the thick collagen fibers. These structures reduce the effective diffusion distance of the water perpendicular to the axis of the fibers. For the intra-axonal compartment, the apparent diffusion coefficient perpendicular to the nerve axis is strongly dependent on the diffusion time (Figure 5). A model for restricted diffusion in cylinders,¹⁶ was used to interpret the results. In this way the intra-axonal inner diameter of the axon was estimated at $7.5 \pm 1.5 \mu\text{m}$ ($n = 3$). This value is in agreement with the known mean inner diameter of the rat sciatic nerve axons of $6 \pm 1 \mu\text{m}$.¹⁷ For the measurement of diffusion in multi-compartment systems the ^2H DQF technique is unique, since it enables the observation of each compartment independently and avoids multi-parameter fitting of the experimental data.

4 ^2H DQF NMR OF CARTILAGE

Cartilage is composed of a solid matrix of collagen fibrils, proteoglycans and water. The collagen fibrils are arranged in fibers and bundles, which may have random orientations or may be aligned along a major axis. In both cases ^2H DQF spectra are observed, yet only in the latter case the lineshape depends on the orientation of the sample in the magnetic field.

For nasal cartilage the DQF spectra did not change as a function of the orientation of the sample in the magnetic

Figure 6 A representative set of observed (dotted line) and calculated (solid line) ^2H DQF spectra of bovine nasal cartilage immersed in D_2O . For the calculated spectra a single set of parameters was used: $\langle\omega_Q^{\text{loc}}\rangle/2\pi = 110 \text{ Hz}$, $\Delta\omega_Q^{\text{loc}}/2\pi = 73 \text{ Hz}$ and $R_2 = 63 \text{ s}^{-1}$. (Reproduced from Ref.⁷ by permission of Academic Press)

field, indicating local order.⁷ A representative set of lineshapes obtained at different τ values is given in Figure 6. Both the intensity and the shape of the spectra vary considerably for

the different τ values. For longer values of τ , the formation of ‘wiggles’ is apparent. As was mentioned in the Theoretical Introduction, these oscillations have intervals of $1/\tau$ and are due to the heterogeneity of the system.

The series of DQF lineshapes obtained for different creation times was fitted using a set of three parameters: the average residual quadrupolar interaction $\langle\omega_Q^{\text{loc}}\rangle/2\pi = 110\text{ Hz}$, its standard deviation $\Delta\omega_Q^{\text{loc}}/2\pi = 73\text{ Hz}$ and a transverse relaxation rate of 63 s^{-1} . The large standard deviation indicates that we are indeed dealing with a heterogenous system.

In articular cartilage the DQF lineshape is orientation dependent, indicating macroscopic order in the tissue. In order to obtain the detailed distribution of the fiber orientations, an image that contains the spectroscopic information has to be obtained. The pulse sequence for one-dimensional (1D) ^2H DQF spectroscopic imaging is identical to equation (1), with phase encoding gradients being applied during the DQ evolution time, t_{DQ} thus taking advantage of the relatively long ^2H DQ relaxation time and the doubling of the effect of the gradients applied during this period. The image obtained, together with some individual spectra, is given in Figure 7.¹⁸ Near the bone, the quadrupolar splitting is of the order of 1500 Hz. A smaller splitting ($\sim 400\text{ Hz}$) is detected in the radial zone. This splitting decreases gradually towards the cartilage surface, is lost in the intermediate zone, and is then again observed at the surface. Upon 90° rotation of the plug, the splitting of the calcified and radial zones is halved, while the splitting of the surface zone is slightly increased. This is an indication that the fibers align perpendicular to the bone at the calcified and radial zones and at the cartilage surface become parallel to the bone. In the intermediate zone there is a distribution of orientations around the magic angle and therefore no splitting is observed. These results are well correlated with the known histology of the collagen fibers in articular cartilage, namely they are oriented

perpendicular to the bone in the deep areas of the cartilage, then they bend and align parallel to the bone at the surface.¹⁹

5 ^2H DQF NMR OF BLOOD VESSELS

The mechanical properties of blood vessel walls play a central role in cardiovascular function. The wall of the blood vessel has remarkable elasticity and fatigue resistance. At normal blood pressure the length of the vessel is as much as 40% longer and its circumference is about 30% greater than in the unstressed condition. The blood vessel wall is composed of three layers: the outer layer (the tunica adventitia), the intermediate layer (the tunica media), and the inner layer (the tunica intima). All three layers consist of different proportions of collagen, elastin and smooth muscle fibers, which are responsible for their mechanical properties.

In 2D ^2H DQF spectroscopic MRI a spectrum for each pixel is obtained, thus enabling the mapping of the distribution of the residual quadrupole interaction $\langle\nu_Q\rangle = \langle\omega_Q^{\text{L}}\rangle/2\pi$ within the blood vessel wall.²⁰ Since this property, as well as the τ dependence of the DQF signal intensity, is related to the composition of the tissue, the results can be interpreted as ‘histological’ images. A comparison between the conventional gradient echo image (Figure 8a) and the DQF images (Figure 8b–d) clearly demonstrates the suppression of the free water signal. Furthermore, the ability of the method to selectively display each of the tissue layers allows convenient measurements of the luminal area as well as of the thickness of the layers.

^2H DQF NMR spectroscopy was used to monitor structural changes following the application of strain.²¹ The spectrum of water in the outer layer (adventitia) of coronary and carotid arteries was found to be highly sensitive to the strain exerted

Figure 7 (a) 1D ^2H DQF spectroscopic image of bovine articular cartilage and bone plug, equilibrated with deuterated saline. The plug was measured with the magnetic field perpendicular to the surface. (b) ^2H DQF spectra extracted from the image, at various distances from the cartilage surface

Figure 8 Histological images of a cross section bovine coronary artery. A piece of coronary artery was equilibrated in D_2O saline. A polyacrilamide rod (3.3 mm diameter) was inserted in the vascular lumen and both ends of the artery were tied with silk threads. The axis of the artery was set parallel to the magnetic field. (a) A 2D 2H GRE image of the artery. The image mostly corresponds to the free water in the space between the rod and the tissue, which remained to prevent magnetic susceptibility artifacts. (b–d) 2D 2H DQF spectroscopic images constructed for a width of 100 Hz in the spectroscopic dimension. The use of different colors (yellow for $\nu = 0$ Hz and red for $\nu = 300$ Hz) emphasizes the fact that the images were taken from different frequency regions. (b) 2D 2H DQF image measured at $\tau = 0.3$ ms and frequency of 0 Hz in the spectroscopic dimension. The image consists of water in all layers of artery, but water in the lumen is completely suppressed. (c) 2D 2H DQF spectroscopic image measured at $\tau = 2.0$ ms and $\nu = 0$ Hz in the spectroscopic dimension. Only the water in the inner layer (tunica media) is depicted, and the thickness of the inner layer is 0.9 mm. (d) 2D 2H DQF spectroscopic image measured at $\tau = 0.3$ ms and $\nu = 300$ Hz in the spectroscopic dimension. Only the water in the outer layer (tunica adventitia) is depicted, and the thickness of the layer is 1.0 mm. (Reproduced from Ref.²⁰ by permission of National Academy of Science USA)

on the vessel wall (Figure 9). The average residual quadrupolar interaction $\langle \nu_Q \rangle$ was calculated for each spectrum²⁰ and is given as a function of elongation in Figure 10. The strain sensitivity of $\langle \nu_Q \rangle$ provides us with the possibility to obtain a strain map for intact blood vessels. This is accomplished by the measurement of 2D spectroscopic 2H DQF MRI. An example of such a measurement is given for a fully relaxed and a 55% elongated sample of a bovine coronary artery (Figure 11). In this experiment the average residual quadrupole interaction $\langle \nu_Q \rangle$ was calculated for each pixel and an image was constructed with a color code which represents the value of $\langle \nu_Q \rangle$ for each pixel rather than the usual signal intensity. The blue color in both images demonstrates the relatively narrow spectrum of the tunica media, which is insensitive to strain. In the left image, the green color that dominates the outer layer, the tunica adventitia, corresponds to $\langle \nu_Q \rangle$ values of 350–450 Hz for the unstressed vessel. In the right image the variety of red and yellow colors in the outer layer of the stretched sample reflects larger values of the residual quadrupolar interaction ($\langle \nu_Q \rangle$ ranges between 550 and 800 Hz) associated with regions with higher strain. Apparently, the broad distribution of $\langle \nu_Q \rangle$ is caused by non-uniform strain in the sample. Using a calibration of $\langle \nu_Q \rangle$ vs. the elongation, these images can be interpreted as strain maps.

6 1H DQF NMR: AN APPLICATION TO THE STUDY OF CONNECTIVE TISSUES

The natural abundance of 1H and its superior S/N ratio make it the nucleus of choice for in vivo measurements. As was discussed in the theoretical background section, anisotropic motion of water molecules leads to a non-vanishing 1H dipolar interaction. Water proton dipolar splitting has already been observed in water molecules adsorbed on oriented collagen fibers, and in partially dried tendon at low temperatures.⁹ In intact tissues, owing to exchange between adsorbed and bulk water molecules and proton exchange between water molecules, the residual dipolar interaction is smaller and the large signal of the isotropic water masks the split signal.⁹ In the case of 1H DQF spectroscopy, like in the case of 2H , the isotropic water signal is filtered out, enabling the observation of partially oriented water even at high temperatures when the doublet has already coalesced. There are, however, a few important differences between 1H and 2H DQF spectra. (a) While the 2H spectrum consists only of water signals, that of 1H also exhibits signals from non-exchanging protons of proteins and lipids.²² (b) The ratio between the 1H residual dipolar interaction and the T_2 relaxation rate is considerably smaller than the corresponding ratio of the 2H

Figure 9 ^2H DQF spectra of the outer layer of bovine coronary artery as a function of elongation. The spectra were obtained by subtracting the contributions of the isolated inner layers from that of the intact tissue. (Reproduced from Ref.²¹ by permission of Wiley InterScience)

residual quadrupolar interaction. Thus the resolution obtained in the ^2H DQF is better. (c) The ^1H DQ relaxation time is much shorter than the corresponding value for ^2H , due to ^1H magnetization transfer from the macromolecules. This fact influences the design of the pulse sequences for spectroscopy and imaging. (d) The water ^1H DQF signal intensity is sensitive to the degree of order of the tissue and it rapidly decreases with the temperature due to proton exchange. One should note that for molecules that do not exhibit proton exchange one can see dipolar splitting even in the presence of a small degree of order. An example is the splitting observed in SQ and DQF spectra of phosphocreatine in muscles *in vivo*.²³

Water ^1H DQF spectra have been measured for various connective tissues.²² For bovine Achilles tendon (Figure 12),⁸ when the tendon's long axis is parallel to the magnetic field, the spectrum consists of a well resolved doublet at low temperatures, with a splitting of about 900 Hz, which coalesces at room temperatures. Fitting the results to equations (4a) and (4b) gave a temperature independent residual dipolar interaction (ν_D) of 300 Hz, and proton exchange rates of $k = 1.75 \times 10^3$, 3.5×10^3 and $6.0 \times 10^3 \text{ s}^{-1}$, at 1.5°, 24° and 41 °C, respectively. In the perpendicular orientation, ν_D is reduced by about a factor of 2. Performing the same analysis for articular cartilage,²² with the magnetic field perpendicular to the bone surface, ν_D of 40 Hz is obtained.

In standard imaging techniques connective tissues appear with a very low S/N ratio, due to the short T_2 associated with

Figure 10 The average quadrupolar interaction (ν_Q) as a function of elongation. The calculation was performed on the full set of spectra shown in Figure 9. (Reproduced from²¹ by permission of Wiley InterScience)

these tissues. As the DQF method exclusively detects ordered structures, it is suitable for selectively imaging these tissues. A pulse sequence, which is suitable for the ^1H DQF MRI experiment, is illustrated in Figure 13.²⁴ Unlike in the case of ^2H DQF imaging, because of the short ^1H DQ relaxation

Figure 11 Two images that display a 2D map of the average ^2H quadrupolar splitting, $\langle \nu_Q \rangle$ of a bovine coronary artery, unstressed (left) and 55% elongated (right). In the magnet the artery, equilibrated in D_2O , was aligned with the external magnetic field. The field of view of both images was 0.75 cm. Figure 15 ^1H DQF signal intensity of the intact and the regenerated parts of rabbit Achilles tendons as a function of the creation time τ . Means and standard errors are shown for the intact tendon ($n = 6$). Typical results of 3, 9, 13 and 18 weeks after the tenotomy are shown from three experiments in each. Reproducibility of measurement is similar to that of the intact tendon (ca. $\pm 10\%$ of the mean). (Reproduced from Ref.²⁷ by permission of Wiley InterScience)

Figure 16 Images of a regenerated rabbit leg measured 18 weeks after tenotomy. (a) Transverse GRE T_2 -weighted image. (b–d) Transverse DQF images obtained at: (b) $\tau = 0.4$ ms; (c) $\tau = 1.0$ ms; (d) $\tau = 2.0$ ms. (Reproduced from Ref.²⁷ by permission of Wiley InterScience)

time, the imaging gradients are applied during t_2 ,²⁵ and the DQ evolution time is kept as short as possible.

A comparison between standard ^1H gradient-echo (GRE) MRI and ^1H DQF MRI of an isolated rat tail is shown in Figure 14.²⁶ The rat tail is composed of a central spinal bone, four tendons, muscle, adipose and subcutaneous tissue, surrounded by skin. In the GRE image the muscle, as well as the subcutaneous and adipose tissues, is bright while the skin surrounding the tail has a lower intensity. The four tendons and the bone are black. Inside the tendons, some loose connective tissue appears as thin bright lines. In the ^1H DQF image, measured at $\tau = 0.4\text{ ms}$, only the tendons are depicted with a good positive contrast to the surrounding tissues. When the measurement is repeated at a much longer creation time, the tendons disappear and the skin is depicted. This is in accordance with the spectroscopic result and is a demonstration of the τ contrast mechanism.

In order to assess the application of ^1H DQF MRI to medically relevant problems, a follow up of the healing process of ruptured tendons was undertaken.²⁷ The rupture of the Achilles tendon is a common incident in daily and sport activities. Rehabilitation is a long process and MRI and ultrasonography do not supply enough information regarding the state of the tendon. The experiment presented here was performed on tenotomized (ruptured) rabbit Achilles tendons. After tenotomy, the animals were allowed unrestricted activity in the cage. At different times both the ruptured leg as well as the healthy one, which serves as a reference, were dissected en bloc. After imaging the Achilles tendons were excised and spectroscopic measurements were performed.

The dependence of the DQF spectrum on the creation time was measured for intact tendons as well as for tendons during the healing process. The results are given in Figure 15. Three weeks after tenotomy, hardly any DQF signal is detected from the tendon. The signal gradually regains its intensity but is still far from normal even 18 weeks after the rupture. Moreover, τ_{max} , the creation time where a maximum intensity is observed, is prolonged from 0.4 ms for intact tendons to 1.0 ms at 9 weeks. Concomitantly with the increase of the ^1H DQF signal intensity, τ_{max} is shortened, and like the intensity, it does not reach its original value even after 18 weeks.

In the conventional GRE T_2 weighted image of the ruptured lower leg, 18 weeks after the tenotomy of the Achilles tendon, all the tendons have very low signal intensity (Figure 16). In the DQF image measured at $\tau_{\text{max}} = 0.4\text{ ms}$ the intact tendons as well as the ruptured Achilles tendon appear with a positive contrast. On the other hand, in the DQF image measured at τ of 1.0 ms, only the Achilles tendon is depicted. This is in line with the spectroscopic results obtained for τ_{max} during the healing process. At a creation time of 2 ms, only part of the Achilles tendon is observed. We assume that not all parts of the tendon have healed to the same degree and the technique is sensitive enough to depict such differences.

The ^1H DQF imaging method was recently applied to the study of human joints on a clinical MRI scanner.²⁸ Although these results are very preliminary they indicate that the method has a potential for clinical applications.

1 INTRODUCTION

NMR studies of filamentous bacteriophage coat protein have been technically challenging and scientifically fruitful; they have provided many opportunities to develop new NMR methodology as well as to learn about structural and membrane proteins, classes of proteins which differ substantially from the globular proteins that receive the vast majority of attention in structural studies by multidimensional solution NMR spectroscopy and X-ray crystallography. The structural biology of coat protein is complex, especially considering that the protein has only 45–50 residues. It is the most abundant product of the small viral genome and, perhaps because of that, it expresses several distinct biological functions.^{1,2} The polypeptide actually encoded by the viral gene VIII, procoat protein, inserts into the cell membrane,³ where processing by bacterial leader peptidase removes the leader sequence from the N-terminus of the protein.⁴ Many copies of the membrane-bound form of the coat protein accumulate within the cell membrane prior to their assembly into the outer coat of the virus particles as they are extruded through the cell membrane. During the course of the viral life cycle the product of gene VIII goes from a preprotein, to a membrane protein, to a DNA-binding structural protein.

Class I filamentous bacteriophages (fd, M13, f1) have important roles that extend beyond their own life cycle, because they are widely used in molecular biology as essential components of experimental methods for DNA sequencing, site-directed mutagenesis, and other procedures. A major new application to biotechnology results from the display of foreign peptides and proteins over the surface of the virus particle by inserting their sequences near the N-terminus of the coat protein.⁵

Comparisons among all of the various coat protein species have been made in the course of the NMR studies, especially between the structural form in the virus and the membrane-bound form, between procoat protein and mature coat protein, and between the proteins from class I and class II bacteriophages (e.g. Pf1). The flexibility of NMR spectroscopy is demonstrated by its ability to show how differences between the membrane-bound form of coat protein and the structural

form of coat protein in the virus reflect the structure and dynamics of the protein, and these are directly related to its biological roles. Although neutron⁶ and X-ray fiber^{7,8} diffraction have played important roles in describing the structure of coat protein and the packing of coat protein and DNA in the virus particles, none of the forms of coat protein have been crystallized. Also, none of the forms in aqueous solution are suitable for multidimensional solution NMR experiments. The difficulties encountered in studying the various coat protein samples by the conventional methods of structural biology provide a great deal of motivation for the development of NMR methods suitable for proteins in supramolecular structures, including DNA–protein and membrane–protein complexes. The NMR studies are feasible even though some forms of the protein exist only transiently in vivo, because all of them can be prepared in vitro as isotopically labeled samples suitable for investigation by NMR spectroscopy, by utilizing solid phase peptide synthesis, isolation from virus particles, and expression in plasmid-containing bacteria.

2 STRUCTURAL FORM OF COAT PROTEIN IN VIRUS PARTICLES

Filamentous bacteriophage particles reorient neither rapidly nor isotropically in solution because of their large size (10^7 Da) and highly elongated shape (9×900 nm). The NMR spectra in Figure 1(a) and (c) demonstrate that conventional high-resolution solution NMR methods are not applicable to proteins, no matter how small, that are immobile on NMR timescales because they are constituents of supramolecular structures.⁹ However, the ^{13}C and ^{15}N NMR spectra of coat protein in fd bacteriophage in Figure 1(b) and (d) demonstrate that the combination of selective isotopic labeling of dilute nuclei and high-resolution solid state NMR methods can successfully replace rapid molecular reorientation as a line-narrowing mechanism. Although magic angle spinning in combination with cross polarization and proton decoupling¹⁰

gives narrow single-line spectra, it is at the expense of the considerable information in the anisotropic chemical shift and dipolar interactions. Nonetheless, the finding that each of the tryptophan (Trp)-26-labeled samples have a single resonance line in Figure 1(b) and (d) provides strong evidence that all coat protein subunits have the same conformation and orientation in the virus particles.

Uniaxial sample orientation is an alternative to magic angle sample spinning as a way to obtain single-line resonances in solid state NMR spectra of polymers,¹¹ with the important advantage that the anisotropic information present in the nuclear spin interactions is retained and expressed in the observable spectral parameters. It is suitable for proteins that are immobile and oriented along the direction of the applied magnetic field.^{12,13} Coat proteins in filamentous bacteriophages are very well suited for this approach, since their structured residues are immobilized by interactions among the protein subunits, and the virus particles behave as rigid cylinders that orient spontaneously with their filament axis aligned with the direction of the applied magnetic field. Peptides and proteins in lipid bilayers can be macroscopically oriented between glass plates for NMR studies,¹⁴ and these samples have been valuable in characterizing the membrane-bound forms of Pf1¹⁵ and fd¹⁶ coat proteins.

The ^{15}N spectra from oriented bacteriophage samples in Figure 2(d) and (h) have resonances with frequencies that reflect the orientations of the amide nitrogens, and hence the peptide bonds, with respect to the direction of the applied magnetic field. Nearly all of the amide resonances in the uniformly ^{15}N -labeled sample of oriented fd [Figure 2(d)] have frequencies near that of the principal element of the chemical shift tensor aligned approximately along the N–H bond.¹⁷ The helical protein subunits are arranged along the filament axis, therefore the N–H bonds of the peptide groups are approximately parallel to the helix axis. There is some spread among the overlapping chemical shift frequencies because of variation and tilt of the α -helix.¹³ In the spectrum of the selectively ^{15}N [Leu]-labeled virus sample in Figure 2(h), the two resonances are well resolved without interference

from the overlapping resonances from the rest of the protein; their resonance frequencies reflect the two distinct orientations for these residues, although both have their N–H bonds approximately parallel in the virus particle. The dramatic effects of sample orientation on solid state NMR spectra can be seen by comparing the spectra in Figure 2(c) and (d) for uniformly ^{15}N -labeled coat protein and those in Figure 2(g) and Figure 2(h) for selectively ^{15}N [Leu]-labeled coat protein. The chemical shift powder patterns in Figure 2(c) and (g) show that most, but not all, of the residues in coat protein are immobile in the virus particles. With only two ^{15}N amide sites contributing to the powder pattern in Figure 2(g) there can be little doubt that both Leu-14 and Leu-41 have immobile peptide bonds. The situation for the entire protein, as seen in the uniformly labeled sample, is more complex, since the narrow resonance intensity near the isotropic position in Figure 2(c) indicates that some of the residues other than Leu-14 and Leu-41 are mobile on the timescale of the chemical shift anisotropy interaction, which is 10^4 Hz. There are a few mobile residues near the N-terminus of coat protein in the virus particles.¹³

Data derived from oriented spectra, such as those in Figure 2, provide the spectral parameters used to determine the orientation of each peptide plane of the protein relative to the axis defined by the direction of orientation of the sample and the applied magnetic field. These spectral parameters, which can be chemical shift frequencies, dipolar couplings, quadrupolar couplings, or others, define restrictions on the orientations of the spin interaction tensor, and its associated bond or molecular grouping, consistent with the experimental data. It is possible to determine the orientations of peptide planes to within a few degrees by solid state NMR spectroscopy and, therefore, to determine the three-dimensional structure of a protein in this way. Complete polypeptide backbone structures require that several spectral parameters be measured to characterize the angles between each of the peptide planes and the direction of sample orientation. These measurements have been used to derive the model for coat protein in fd virus shown in Figure 3.¹³

3 MEMBRANE-BOUND FORM OF COAT PROTEIN

Many of the difficulties associated with NMR studies of membrane proteins can be overcome with a concerted approach that combines the methods of high-resolution solid state NMR spectroscopy on samples of membrane proteins in bilayers with those of multidimensional solution NMR spectroscopy on samples of membrane proteins in

micelles.^{18,19} fd and Pf1 coat proteins have had important roles in the development of this methodology.^{15,16} In this approach, the secondary structure of the protein is determined on the basis of internuclear distance measurements in micelle samples, and the arrangement of the major elements of secondary structure is derived from measurements of angular parameters in oriented bilayer samples.

Membrane proteins display a wide variety of intramolecular dynamics. fd coat protein in micelles was the first system to display heterogeneous backbone dynamics where the resonances from mobile residues could be clearly distinguished from the rigid residues on the basis of multiple relaxation parameters,²⁰ most dramatically with ¹⁵N-labeled samples in micelles by the observation of large negative heteronuclear ¹H/¹⁵N NOEs,²¹ as well as in bilayers with the observation of narrow isotropic resonance intensity in ¹⁵N solid state NMR spectra.²² The comparisons between solid state NMR and solution NMR results can be particularly revealing, since there are residues that are mobile on the slow timescales of solid state NMR powder pattern lineshapes but are immobile on the rapid timescales of solution NMR relaxation measurements. These results have been supplemented by measurements of amide N–H exchange rates throughout the polypeptide in micelles.²³

A fairly complete picture of the dynamics of the membrane-bound form of coat protein has emerged from the NMR studies. Residues 1–5 at the N-terminus are mobile on the 10^{–9} s timescale of NMR relaxation measurements as well as the 10^{–4} s timescale of solid state NMR lineshapes. Proline-6 is immobile in all forms of the protein on timescales as slow as 10^{–4} s, and the structured portion of the protein begins at this residue. Solid state NMR lineshapes show that Tyr-21 has some mobility, even though homonuclear ¹H NOEs indicate that it is part of a stable structure. The two helical segments, residues 7–20 and residues 23 and 42, appear to be rigidly structured on all timescales. The C-terminal residues 44 through 50 show evidence of mobility on various timescales, depending on the temperature.

Multidimensional solution NMR methods can be applied to the membrane-bound form of coat protein in micelles in aqueous solution.^{15,16,20,24,25} Isotopic labeling is especially important for a slowly reorienting protein in micelles, and this need led to coat protein being the first uniformly ¹⁵N-labeled²⁶ and uniformly ¹⁵N/²H-labeled²⁷ protein for multidimensional NMR experiments. The choice of detergent and its concentration are crucial aspects of sample preparation, and have been problematic for solution NMR studies of fd coat protein in micelles.²⁸ The spectrum in Figure 4 shows that single correlation peaks can be resolved and assigned for fd coat protein in micelles. Three-dimensional spectra show backbone NOEs that are consistent with extensive helical secondary structure in the protein.^{19,25} This can be demonstrated with the leucine residues, Leu-14 and Leu-41, the same residues labeled selectively to obtain the data in Figure 2. ¹H/¹H strips at ¹⁵N chemical shifts corresponding to Ser-13, Leu-14 and Gln-15 show the presence of NOEs between resonances from hydrogens on adjacent amide nitrogens, α -carbons, and β -carbons; these residues are part of an amphipathic helix that lies in the plane of the lipid bilayer. Lys-40, Leu-41 and Phe-42 also exhibit these characteristic NOEs and are a part of the hydrophobic transmembrane helix. Numerous other NOEs observed for residues 13–15 and

Figure 4 Two-dimensional $^1\text{H}/^{15}\text{N}$ heteronuclear multiple quantum correlation spectrum of uniformly ^{15}N -labeled fd coat protein in micelles. (Reproduced by permission from McDonnell et al.¹⁶)

40–42 are between $\text{NHC}_\alpha\text{H}(i, i + 3)$ and $\text{NHC}_\alpha\text{H}(i, i + 4)$ sites, strongly supporting the presence of helical secondary structure for both Leu-14 and Leu-41 of fd coat protein in micelles.

Since it is possible to prepare both oriented and unoriented samples of proteins in fully hydrated phospholipid bilayers, a wide variety of spectral parameters can be resolved and measured from single-line and powder pattern spectra obtained on these samples.¹⁶ The ^{15}N chemical shift powder patterns from unoriented samples of uniformly [Figure 2(a)] and selectively ^{15}N -labeled fd coat protein in lipid bilayers [Figure 2(e)] indicate that the membrane-bound form of the protein has both mobile and rigid backbone sites. The amide groups of both Leu-14 and Leu-41 are immobile in membrane bilayers because the powder pattern spectrum in Figure 2(e) shows little evidence of motional averaging. However, the spectrum in Figure 3(a) from the uniformly ^{15}N -labeled coat protein in bilayers has substantially more isotropic resonance intensity than the same protein in virus particles [Figure 2(c)], which indicates that there is a difference in dynamics between these two forms of the protein.

The resonance bands in the spectrum of an oriented bilayer sample of uniformly ^{15}N -labeled fd coat protein [Figure 2(b)] occur near the positions expected for transmembrane and in-plane helices. Better spectral resolution is available from selectively labeled samples. Since the secondary structure for the two leucine residues is established as helical by NOE data as discussed above, the resonance frequency of each nitrogen site can be used to establish the orientations of the two helices relative to the plane of the bilayer. The spectrum in Figure 2(f) of [^{15}N]Leu-labeled coat protein in oriented bilayers has one line with a resonance frequency near the

parallel orientation for the N–H bond and a second line with a resonance frequency near the perpendicular orientation for the N–H bond, indicating that the hydrophobic helix spans the bilayer because the N–H bond of one of the leucine residues is parallel to the direction of orientation and that the amphipathic helix is in the plane of the bilayer because the N–H bond of the other leucine residue is perpendicular to the direction of orientation.

4 PROCOAT PROTEIN

The 73-residue procoat protein, which includes the 23-residue N-terminal leader sequence, was prepared by solid phase peptide synthesis with two ^{15}N -labeled residues, one in the leader sequence and one as a control in the rigid hydrophobic helix found in the mature protein.²⁹ Spectra from these labeled species in micelles and bilayers qualitatively characterized the dynamics of these proteins. Ser-20- a residue near the N-terminus of the leader sequence, was found to be mobile on both the 10^{-4} and 10^{-9} s timescales, while residues –13 through –10, all of which are in the midsection of the leader sequence, were found to be rigidly held on all timescales. Residues at or near the cleavage site of leader peptidase are mobile, in particular Ala-1– and Gly-3+ are mobile on the basis of both solution and solid state NMR data. The mobile region of procoat protein near the cleavage site may be necessary for removal of the leader sequence to form the mature protein. In separate solid state NMR experiments on an oriented sample of procoat protein in lipid bilayers, the ^{15}N resonance frequencies for labels in the leader sequence are shown to be in the plane of the bilayer.

5 COMPARISONS AMONG THE VARIOUS FORMS OF COAT PROTEIN
